The quills and tail-feathers are brown, clouded with a darker shade of the same colour, and the tail is pointed and consists of eighteen feathers, the two parts folding upon each other as in the common fowl. The tarsi are long and strong, armed with short but sharp spurs in both the sexes, but the female is without the wattles and horny appendages, and of a brown colour. The naked parts of the feet are bluish white, the toes and claws long but not much arched, and the hind toe is articulated so far up on the tarsus as not to touch the ground in walking. The whole air of the bird, which is rather larger than the common fowl, is expressive of vigour, and that structure of the feet to which we have alluded points out that it is a swift runner, as these organs approach very nearly to those of some of the more flat-footed of the running birds. The habits are not much known, but the length of the toes would indicate that the bird frequents the margins of the waters, or otherwise upon soft and boggy grounds. Hitherto it has been found only in the north of India, but how far its geographical distribution extends we are uninformed. It does not appear, however, that there is any trace of it in central or in western Asia, though we want information respecting the natural history of those mountains which, extending from the Himalaya to the Altaian

ridge, divide the Chinese rivers from those that flow westward to the central lakes.

**CREPTONYX**—crested pigeon of Latham. The birds of this genus are of small size, not exceeding that of the common quail. They are inhabitants of India and the eastern islands, but they are hiding birds of the margins of the close jungles, and little is known of their manners. As this species (for there is only one species known with certainty) bears some resemblance to birds of several genera, it has been called by different names, such as the green partridge, the green grouse, and some others; but its generic characters do not warrant its union with any of these. The characters are: the bill stout, strong, and compressed; the two mandibles of equal length; the edges of the upper one straight, except a little curvature towards the point. The nostrils longitudinal, placed in the middle of each side of the base of the upper mandible, and partially covered with a naked membrane. There are three toes turned to the front, partially to their bases with a small membrane, and the hind toe is without a claw, articulated high on the tarsus, and does not touch the ground in walking. The tarsi are long, and without any spurs in the male: the wings are short, rounded, and hollow, the first quill is very short, and the fourth, fifth, and sixth are the longest in the wing. The known species,

*Creptonyx cristata*, inhabits the Sunda islands, and also many parts of the south of Continental Asia. The upper parts are of a bright green colour. Six black feathery bristles rise in the form of a ruff on the front; the top of the head is white, but furnished with long plumes of a reddish colour, which form a loose crest inclining over the occiput. The cheeks and neck are black; the coverts of the wings brown of various shades, varied with russet and black. The under parts are blackish violet; the bill greyish above and fawn-coloured on the under side; the irides yellow, and the feet fawn-coloured. The tail is of mean length, and carried flat, not folded together as in poultry. The female is of a dull green colour on the upper part; the naked skin round the eyes is reddish; the wings resemble those of the male, but are less bright in the colours. The under parts are blackish brown, and the feet are reddish. This last circumstance has caused the sexes to be described as separate species; but the truth respecting them is now pretty well ascertained. A smaller species of a red and yellow colour, between five and six inches in length, while the green one is about ten inches, has occurred as a museum specimen, and been reported to be from the Guzerat, or rather from that extensive tract of ground near the Runners of Cutch, which is seasonally flooded, and which is at other times so very rich in ground birds of various genera; but we believe nothing is known with certainty respecting this bird, as to even where it came from, or whether it be or be not an accidental variety.

The species which we have hitherto enumerated may be said to comprise one of the natural groups of the gallinidæ with regard to geographical distribution. In a native state they are not found to the westward of the Persian mountains, or of that cross ridge in central Asia to which we have alluded; for though the common pheasant is described as having been brought from Colchis, the probability is that it was an imported species there, and it does not appear to have been found in the west of Asia further to the south. Those Asiatic birds excel all the rest of the

order in the beauty of their plumage, in the form of their bodies, and in the boldness and pugnacity of the male birds, both in their affairs of honour and in defence of the females and young. There are differences of flavour and other qualities in the flesh; but all the species are not only eatable, but wholesome, and, generally speaking, superior. The more they are in a state of nature, the flesh has always a finer flavour, but it is more tender, and also more abundant when they are domesticated. There are also degrees of hardness among them, especially on their introduction into climates colder than their native ones; but still they are all what might be considered hardy birds; and there is probably no species of them but which might be introduced with advantage into all climates, excepting those which have the very extreme of severity. They are all polygamous; their broods are numerous; and as in polygamous animals, the number of females always exceeds that of the males; they are equally valuable for their eggs as for their flesh; and on both these accounts, as well as on account of their beauty, they are eminently deserving of attention. There still remain several genera to be noticed, as birds of the warmer climates of Africa and America, before we come to speak of those of the cold and temperate regions of the northern hemisphere.

**GUINEA FOWL** (*Numida*). This is originally an African species, or at least a native of the south west of Asia only, in addition to the African continent. It has however been pretty generally introduced into various parts of Europe, Asia, and America, as a domestic bird. In a domesticated state, the Guinea fowl (which is also called the pintado) is not so profitable as the common fowl, chiefly because the females are much less attentive to their young, and the number bred with the same labour is consequently smaller.

The characters of this bird are: The bill short and stout; the upper mandible curved, convex, arched in the culmen, and covered at the base by a warty membrane; there is a sort of carunculated wattle suspended from the under mandible, and the nostrils are placed in the membrane, at the base of the upper mandible, and half covered by cartilage; the head is generally naked, or thinly scattered with a few hairs, and with a strong callus, or horny crest. Some of the species however, which we shall notice afterwards, are distinguished by crests of feathers; the tarsi are smooth, and the feet have four toes, three to the front, which are united to their bases by a short membrane, and one in the rear articulated higher up on the tarsus than the front ones; the tail short, and drooping towards the ground, the external feathers on both sides being very short, and gradually increasing in length to the fourth on each side; there are at least three species, if we admit the possession of a crest of feathers as a sufficient distinction, and the common species, as is the case with most of the domesticated gallinidæ, is broken into several coloured varieties, which do not however appear to be deserving of particular notice, at least as species.

The common Guinea fowl (*N. meleagris*) has the body greyish blue, sprinkled with small white spots; head and upper part of the neck naked, a conical tubercle, with its tip reflexed on the crown, and a broad geminated membrane near the gape. One variety has the breast white, and another has the whole body whitish, with rounded white spots: other

varieties also occur, and a hybrid has been produced between a male pintado and a domestic hen. The young are pretty birds, somewhat resembling red partridges at an early age: the adult male is much larger than the common cock, and measures about twenty-three inches in length; the male has a loose wattle of a bluish colour, but that of the female is red. These birds in a wild state associate in numerous flocks, manifesting a partiality to marshy and morassy situations, where they subsist almost wholly on insects, worms, and seeds, laying about nine eggs, but breeding probably more than once in the year. In many of the scorching districts of Africa, in Numidia for instance, they fly in troops during the day, and perch at night on trees. They abound in the fertile plains of Arabia, according to Niebuhr, and are so numerous near Tahama, that the children knock them down with stones and sell them in the town. In the year 1508, vast numbers of them were transported to America by the Genoese; they have now so greatly multiplied, and become so habituated to the climate, that in the Spanish possessions they roam at liberty in the midst of the savannahs and woods. They sustain without injury the cold of our northern climates, notwithstanding the great heat of their native country, and might possibly be as successfully introduced into our woods and parks as the pheasant; but it is very troublesome to get them to incubate and rear the young in the poultry yard, as they frequently desert their charge, and drop their eggs under hedges, or in other concealed places. The hen pintado when sufficiently fed will lay about one hundred eggs, if care be always taken to leave one in the nest. The eggs of the pintado are smaller than those of the common fowl, of a rounder form, reddish white, obscurely freckled with a darker colour, and are considered a very delicious morsel. As ancient and modern epicures have boasted the flavour of this species, it has been reared for the table in all ages, and frequently by the intervention of the common, or of the turkey hen, either of which proves a more vigilant and careful nurse than the female pintado.

When Guinea fowl are kept in a domestic state, they do not seek their own food with the same assiduity as common poultry; and thus they require some attention in this respect, which adds to the expense of keeping. Once or twice a day they must be regularly supplied with food, which consists of buckwheat, barley, or millet; they eat when in the fields grasshoppers, worms, beetles, and ants, and cut up and destroy the tender buds and flowers. They eat considerably more than the common poultry, probably, in consequence of the shorter length of their intestines. A male pintado will serve for ten females. The female generally lays at the latter end of May or the beginning of June, and the eggs are usually from eighteen to twenty-four in number: the shell of the egg is of a yellowish white colour, spotted with small brown points, and is very hard; they are deposited by the female in a retired place, under some bush; she seldom sits with any assiduity, nor when the young are disclosed does she display any great affection for them; it is therefore found more profitable to have their eggs hatched by a common hen: the incubation lasts three weeks, or rather better. As we before hinted, the young are very delicate and difficult to bring up, requiring much attention in the article of food; they should be placed where there are insects, and in a dry situation. On the top of the

head, the casque, and the barbels of the lower jaw, are not distinguished before the birds are six or seven months old. Near the time these appendages begin to make their appearance, and the epoch is critical for the young pintados, they become liable to maladies, from which they cannot be preserved but by great care and proper nourishment. A considerable difference between the pintado hen and the common one is, that the intestinal tube is much shorter in proportion in the last, being but three feet long, without reckoning the cæca, which are six inches each: they proceed widening from their origin, and receive the vessels of the mesentery, like the other intestines. The largest intestine is the duodenum, which is more than nine lines in diameter; the gizzard is like that of the hen, and small gravel stones are found there, as in that bird; indeed, nothing else is found there sometimes, the consequence apparently of the animal having died in a languishing state, and passed the latter moments of its life without eating: the internal membrane of the gizzard is very much wrinkled, and very slightly adherent to the nervous tunic, and of a corneous substance, or something very analogous to it.

The crop is about the size of a tennis-ball when inflated; the intermediate canal between the crop and gizzard is of a harder and whiter substance than that part of the intestinal tube which precedes the crop, and does not exhibit nearly so great a number of apparent vessels: the heart is more pointed than it is commonly found in birds, the lungs are as usual; it has, however, been remarked in some subjects, that on blowing into the trachea, to put the lungs and air-vessels in motion, that the pericardium, which appears more loose than usual, became inflated as well as the lungs. In the cavity of the thorax, the trachea receives two small muscular cords, about an inch long, and two-thirds of a line broad, which are implanted there on each side. These two muscles adhering on one side to the bottom of the trachea, and on the other to the clavicles, are peculiar to all the species of gallinidæ; they serve to keep the trachea fixed to the middle of the aperture of the thorax: the lower part of the trachea, and the lower larynx of the pintados, differ very considerably from these same parts in cocks and pheasants. The entire tube of the trachea in the pintados, from the glottis to the distance of an inch from the lower larynx, is formed of complete rings, in the intervals between which are membranes. This part of the trachea is susceptible of being elongated or shortened by two pair of muscles, which accompany it through its whole length; but at the distance of an inch from the lower larynx the rings are broad, perfectly cylindrical, and soldered as it were one upon the other. On each side of this tube towards the lower part are five membranes, which are followed by three rings of the lower larynx, from which the bronchiæ depend. These last are formed of flat semi-rings, which gradually diminish in length: there are thus some imperfections connected with the Guinea fowl as an inhabitant of the poultry yard; but where elegance and variety, as well as mere profit, are objects of consideration, it can be advantageously introduced.

The crested Guinea fowl (*N. cristata*) is chiefly known as an African bird. It is less in size than the common Guinea fowl: the bill is horn colour, furnished at the base of the upper mandible with a bluish cere in which the nostrils are placed. It has no carunculated appendage to the lower mandible like

the common species ; but there is at each side of that mandible a longitudinal fold, forming a sort of small appendage ; the throat, the upper part of the neck, and the hind portion of the head are denuded of feathers, and the naked skin is deep blue on the latter part and sides of the neck ; it is greyish blue in the region of the ears ; and it assumes a crimson tint toward the fore part of the neck. This species gets its name from a crest of feathers on the upper part of the head : the plumage is black, powdered over with very small spots of bluish white bordered with bright blue ; the neck and breast are black, and the crest on the top of the head is also black, and composed of downy feathers with their webs quite disunited : the wing-coverts are blackish brown, some of the secondaries being marked with four white rays, and others having their exterior webs bordered with black : the beak is ash colour, the cere bluish and smooth, and the naked membrane on the head and neck is thinly scattered with very delicate hairs. The length of the male bird is about eighteen inches.

This species is represented as inhabiting the hottest parts of the interior of western Africa, where they are said to be found in very large flocks upon the margins of the sandy deserts. One of these flocks consists of some hundreds, made up of many united broods ; for it appears that these birds, though when domesticated they do not agree well with the other gallinidæ, are yet very sociable with each other. Their numbers are so great that they make the deserts re-echo with their discordant cries. Towards the rising of the sun and close of day their piercing cries are most frequently heard : the manners of these birds are like those of the last and the following species, and they equally feed on all kinds of grains, worms, insects, and berries.

The *mitred Guinea fowl* is distinguished from the others by a horny crest or casque on the top of the head. Its manners and habits are similar to those of the common Guinea fowl ; its cry differs very little from that of that bird, and is equally discordant and continuous ; in size it is alike, measuring twenty-one inches ; its casque rises about an inch and a half above the top of the head, in the adult state ; but in the young birds it is less curved backwards, and less angular. There are no distinct wattles in this species, nor any fleshy appendage to the lower mandible, but merely two slight folds of skin, one directed from near the eye toward the gape, and the other from the same point down the side of the neck ; these, however, are but little produced, and therefore they are not very conspicuous. This species or variety has been found in the island of Madagascar, and it is pretty generally distributed over the continent of Africa, at least such is the opinion of naturalists.

We believe that we have now enumerated all the principal species, and most of the leading varieties of the gallinidæ of the eastern world, which may be considered as having their native localities confined to the southward of the central mountains of Asia, and the Mediterranean. They form as it were a southern division of the order in this hemisphere ; there is also what may be regarded as forming, in a geographical point of view, a middle latitude division, which are found in the wild state, in the same localities as one or another of those which have been described, and also in higher latitudes than any of the others are met with in a state of nature ; but before we advert to these, it will be necessary very shortly to notice the

southern division of those which inhabit the American continent, though from what we have already remarked in the articles *ALECTORIDÆ* and *CURASSOW*, we may confine our present notice to a mere enumeration of the species ; they all belong to the family

*ALECTORIDÆ* ; and fall under the following divisions :—

*Ouarax*, the *pauri*. These birds are inhabitants of the warmer parts of tropical America. They are large birds, and when in a state of nature and undisturbed by human intrusion, they are very tame, on which account Buffon, and some others, have most incorrectly brought a charge of stupidity against the birds. This is very incorrect ; for though they are birds of gentle manners, very easily tamed, and capable of much attachment, when in a state of domestication, they are most attentive to their young ; and although in the openings of the wild woods they are quite unsuspicious, and allow sportsmen readily to get within shot of them, yet, when the neighbourhood becomes peopled, they become shy.

The male bird of this species measures about two feet ten inches in length, and in size and weight it very much resembles the domestic turkey. It has the bill very short and stout, and considerably hooked. This bill is covered with a membrane at the base, which extends a considerable way up the forehead, and is met by soft and tufted velvety feathers. In this naked membrane, immediately at the base of the bill, there is a tubercle, of an oval shape, about the same size as the bird's head. This tubercle is of a bright blue colour, and of the hardness of stone, on which account the French give them the name of the "stone birds." (*Oiseaux à pierre*.)

The species to which we allude (for there are more than one), is the *Craz pauri* of Linnæus. According to the accounts given by those who have good opportunities of observing, this bird nestles on the ground, and leads about its young, and calls them to it by a cry, much in the same manner as the pheasants. At first the young live on insects, and then, when they grow large, on fruits, grains, and, in fact, on every thing on which poultry can be fed. When in a state of domestication, and she has become well accustomed to the climate, the female brings up her little ones extremely well ; but it often occurs that great quantity of the eggs are abortive, which proceeds from not giving to these birds sufficient liberty. By fastening their wings, and leaving them a large space, shaded on one side, the broods will thrive extremely well. The eggs are white, and about the size of those of the turkey. The hen turkey may be employed both to hatch these eggs and educate the young, as the time of incubation is the same with both birds. The little ones are covered with a brown down, and the globe which should surmount the head is not apparent at this early age. After the first moulting it shows itself, by a small tubercle, which increases in proportion as the bird advances in age. Both the male and female are provided alike with this appendage, but, in the latter, it is somewhat smaller. The globular excrescence which we have mentioned as adhering to the base of the upper mandible, is of a bony texture in the adult birds, and ramified over with grooves. The interior is composed of small cells, which the bird appears to have the power of filling with air through an opening in the interior of the upper mandible ; though what purpose this curious appendage answers in the economy of the birds

as not been explained. The young have it round, but in the mature birds it rises up in a crown, and has some resemblance to a pear standing on the thick end, and is altogether about two inches and a half in height. One of the cries of these birds resembles the syllables *po-hic*, very loud and clear; but they, in common with most of the family, also utter a humming or murmuring sound. The call is common to the two sexes, and it is clear and sonorous, and heard a considerable way off. In the male there are convolutions in the trachea, bearing some slight resemblance to what we meet with in some of the swans and other birds which dabble in the waters; and this renders it probable that the cellular appendage to the bill may answer some purpose analogous to that of the enlargement of the bronchial end of the trachea in these other birds. After the trachea has followed the same direction with the gullet, as far as the entrance of the thorax, it returns upward, over the right great pectoral muscle, at some distance from the crest of the sternum, continues its direction over the entire length of this muscle, forms a curve there in passing to the distance of two lines behind the sternum, over the tunic which retains the entrails; it then proceeds the length of two inches and a quarter over the left pectoral muscle, there makes a turn on the side of the sternum, passes anew behind this bone, above the first curve, then turns anew, follows its direction over the right pectoral on the side of the crest of the sternum, and passes over the right clavicle into the cavity of the thorax. There is a muscle on each side of the trachea, which serves to lengthen or shorten it. The tube adheres, in its entire length, to the pectoral muscle, by a very fine cellular tissue, and is immediately covered by the skin. The upper and lower larynx do not differ from the same parts in the peacock, but a very apparent socle is found at the bottom of the upper larynx, at the aperture of the glottis. The tube of the trachea is composed of slender rings, distant from each other about two lines. The spaces between the rings are membranous. It is understood that this convolution of the trachea is not wholly confined to the male bird, but occurs in the female also, though to a rather smaller extent.

One or two other species of this genus are mentioned; but they do not require a very particular notice. They are:

*Ourax mitu*, which has been improperly confounded with the curassows. It has the upper parts black, with violet and purple reflections, but the margin of each feather dead black, without any reflection, the upper part of the head is covered with short velvety feathers, of dead black, and there is a crest of frizzled feathers, not very long, and of an intense black on the hind head and neck. The coverts of the wings are black, with white tips. All the under parts are brilliant black, with the exception of the belly and under-tail coverts, which are maroon brown. The feet are reddish, and the bill is red, surmounted with a horny casque of the same colour, which runs a little way upon the forehead. The irides are blackish. The length of the full grown bird is from twenty-eight to thirty inches. The young have the black colour less pure, the red in the bill and feet duller, and the casque on the bill less elevated.

Two or three other species have been mentioned, but they are known only as museum specimens, which have no interest for the general reader, and even these are a little confused. Indeed they are not often

seen by the European colonists, even in those countries which they inhabit, as they are much more shy than many of the other gallinidæ, and especially than the curassows. These last are found very generally in the court-yards in Brazil, in Guiana, and in Mexico; but the *pauxis* are rarely seen there, nor are they very common in collections. They inhabit the vast forests with which so great a breadth of the fertile regions of tropical America is covered; and as the only inhabitants of the open parts of those forests are the different tribes of Indians, who range the wild woods with much more ease than Europeans, the birds are chiefly sought after by them as game. With few exceptions, such as the cultivation of a little cassava and Indian corn, those wild tribes subsist entirely upon the produce of the forests; and, aided by the *wourali* poison, and their bows and blowing tubes for throwing arrows and darts, they are very expert marksmen, and can bring down a bird, or arrest the speed of a land animal, with perhaps greater certainty than an European can do with his musket. The poison is of great service to them in this respect, because the least movement with the poisoned weapon very speedily throws the animal into a complete stupor, or kills it, if only a small one. The arrows and darts are so contrived, that the point which is armed with the poison, and of which the hunters keep a store, taking great care to preserve them from damp, is so contrived, that the moment it fastens in the body of an animal, the shaft or handle drops off, so that it may again and again receive fresh points, and bring down fresh game before the hunter takes the trouble of picking up the first ones. We believe that the birds of this genus are the game most highly prized by those Indians, though many of the larger species of parrots are also very good eating, and as they are more in sight than those birds of the deep forest, they fall more to the lot of Europeans in traversing the wilds.

*PENELOPE* (the *Guan* or *Yacou*). This is also a species inhabiting the tropical parts of America, chiefly to the south of the Isthmus, and between the Andes and the eastern sea. *Guan*, or *quan*, and *yacou*, are names given to it by the natives of those countries in which it is found. The systematic name, *Penelope*, is not very well chosen, because it has been applied to the widgeon, a bird which is very unlike the present genus; and the widgeon again got its name from the Greek fable, of a red-headed duck having saved Penelope, the wife of Ulysses, from drowning when she was a girl. It does not appear that either the widgeon, or any bird of the present genus, ever practised so much gallantry; as the names have been generally introduced, however, it would not be advisable to change them.

The characters of the present genus are, the beak of mean length, and nearly straight, depressed at the base, so that the breadth exceeds the height, and with the upper mandible sharp and curved at the tip. The forehead, a space round the eyes and the chin, are bare of feathers; the nostrils are placed on each side of the bill, near the middle of its length, and have only a small part toward the front open; the tarsi are slender, and not longer than the middle front toe; there are three toes to the front, united by membranes at their bases, and one to the rear articulated much further up on the tarsus than the front ones. The first four girdles of the wings are gradually *staged*, or the one regularly longer than

the other, like steps; the fifth and sixth are the longest in the wings, which are, consequently very much rounded. They are also short, so that the birds are incapable of an extended flight. The naked part of the throat is furnished with a sort of wattle, the middle part of which is marked with warts or tubercles. The tarsi are covered with reticulated scales; and this, as well as the peculiar form of the bill, point them out as ground birds, inhabiting moist places and the margins of the waters. Their colours are subject to great variations, in different birds, and in the same bird, in different ages and at different seasons, so that it is exceedingly difficult to determine species and varieties, as difficult indeed as in the case of the common cock; and it is possible that the circumstance of having or wanting a crest may not form a specific difference in the one genus any more than it does in the other. When these birds take to the wing, their flight is near the ground, on the level, and of brief continuance. In the extensive and dense forests of those places in which they inhabit, they perch on the inclined branches of trees, and run so quickly by the aid of their short wings, that a man cannot overtake them. They pass the day concealed in thickets; but they are astir morning and evening, when they resort to the outskirts of the forests, without, however, entering into the open plains, or other exposed situations. They are easily reconciled to domestication; and they subsist on grains and fruits like the rest of the gallinaceous birds. But when they swallow Indian corn, they void grains entire. They may be reared with profit in the poultry yard, for their flesh is excellent; but they are averse to close confinement, and should be allowed to be much in the open air. They utter, in a shrill, but subdued, and nasal tone, the sound of *pee*. They construct nests of small twigs, which they carefully conceal in a close bush or tree near the ground. The eggs are generally about eight in number. They live in pairs, and also in families, which appear very much attached to each other, for if there are several found in a tree, they will remain till they are all shot one by one. When they perch, or otherwise repose, they support the breast on the folded legs. We shall briefly notice the leading species.

*The Crested Guan (P. cristata).* This species was long confounded with the turkeys, with which it has hardly any character in common, except that both are gallinaceous birds. It has also sometimes been called a peacock, to which it has if possible still less resemblance. Buffon gave it the name of *yacou*, which we believe is what it is called by the Aborigines of Brazil, while guan or quan is its native name in some other parts of South America. The upper parts are blackish green, with metallic reflections of olive and bronze colour. The rump and tail-coverts are deep red. A black streak extends from the angle of the lower mandible to the ear. The cheeks are in great part naked and of a bright red colour. There is a small crest of loose feathers on the hind part of the head; and a large pendent wattle hangs from the gorge which is of a fine red colour, and capable of being elongated and contracted according as the bird is excited or not. This appendage is nearly double the size of that on the throat of the turkey; but the bird has the power of withdrawing it so completely, that it scarcely differs from the naked skin of that part to which it is attached. The breast is of an olive colour, and the rest of the under

parts reddish, the margins of the feathers on both being white. The bill is black at the tip and blue at the base; the naked skin round the eyes violet, the iris orange, and the feet are ash-coloured. The length of the full grown male is about two feet and a half. The female is rather smaller, less bright in the colours, and has the feathers on the head, the crest, and the scapulars, bordered with white. The young birds have the head and neck completely covered with reddish downy feathers; three stripes of maroon brown also of downy appearance, one large one along the head and upper part of the neck, and a smaller on each side. The upper parts are deep red clouded with paler, and the under parts are reddish white. In this stage of its growth it has been described as a separate species; but it is now well ascertained to be only the young of this one.

The male in this species, as is the case in many others of the *Alectoride*, has a flexure of the wind-pipe. After having accompanied the gullet to the anterior part of the sternum, the wind pipe, or trachea, rises over the right pectoral muscle; but it advances only two inches in that direction and repasses over the same muscle, and reaching along the crest of the sternum, enters the cavity of the thorax and proceeds toward the lungs. The rings of cartilage in this organ are separated by pretty broad membranes; and toward the larynx it opens like a funnel. The larynx is attached to the process of the *os hyoides*, or bone of the tongue, and consequently it is connected with that organ, as in the pauti, the turkey, and the peacock, while in the common cock, the curassow, and the different species of pheasants, the larynx is not supported by the bone of the tongue, but merely attached to the membranes of the gullet. This difference of structure in the upper larynx of the trachea has a considerable influence on the intonation of voice in the birds; as those which have it fixed to the tongue, are incapable of the same flexibility and clearness of utterance as those which have it free. It must be understood, however, that in birds, the lower or bronchial larynx is the real organ of voice, that is the organ at which the sound they make originates; though of course this original sound is modified by the nature of the tube through which it passes, and also by that of the upper orifice from which it is communicated to the air and rendered audible. A convoluted trachea gives depth to the note of birds, in the same manner as a long tube gives depth to any other wind instrument; and it is also evident that one which is capable of much motion in its several parts, or has one part wider than another, must roughen the sound, and in this bird the last effect is further increased by the upper larynx and surrounding parts being covered by tubercles. We are not, however, to suppose that the peculiar structure of the trachea in these birds is confined to the mere modulation of the sounds which they utter; for these are but a very secondary part of their economy. But they inhabit regions which are seasonably flooded to a very great extent; and though their haunts are not then explorable, it is highly probable that they feed under water, in the shallows, for as they are ground feeders, they cannot well feed anywhere else at those times; and therefore the convoluted and extended trachea in them may enable them to keep the head longer immersed, just as it does in those dabbling birds which have it formed in this manner. But the wilds of the forests

in tropical America are not very explorable at any season, and when flooded they are forbidden grounds, so that we have no means of knowing the conduct of the ground-feeding inhabitants at those times, farther than by analogy, and the analogy is rather loose, as no other countries have exactly the same physical characters.

*The Whitting or Hissing Guan (P. pipile)* varies more in colour than even the former one, and therefore descriptions of it founded on colour are apt to be more contradictory. The upper parts are black with metallic reflections of purple and violet. The nape is furnished with a crest of long thread-like feathers, which are white with black shafts. There is a large white band on each side of the neck. The greater and middle coverts of the wings are white with black tips and shafts. The under parts are black with some streaks of white on the breast. There is a small naked space on the cheek of a blue colour, and the pendent wattle on the throat is also blue. The quills of the wings are black with metallic reflections; the feet are red, and the bill bluish at the base and black at the tip. The full grown male measures about twenty-eight inches. The female is rather smaller in size, and less bright in the colours; and has the feathers of the crest mottled with black and white. The young are of a maroon brown colour, with the naked space round the eyes leaden grey. The feathers in the crest are shorter than in the mature birds, and also brown.

This species ranges from Guiana to Paraguay, and from the base of the Andes to the shores of Brazil; and in a bird extending over so wide a territory, we may expect considerable climatal differences. Accordingly individuals have been mentioned as occurring in Brazil, in which the webs of the quills do not extend the full length of the shafts, but leave a portion of these naked like a spine. Some individuals have been kept in confinement in Europe, in which state they were very quiet and inoffensive birds. The sound emitted by this one is a sort of hissing whistle, not nearly so loud or harsh as that of the former species; and the authorities state that the trachea goes straight to the lungs without any convolution.

*The Marail Guan (P. marail).* This species is called the green pheasant in Guiana. It is a well distinguished species, and remarkable for the brilliant metallic lustre of its plumage. The upper part is rich blackish green; the crest, which is large and tufted, is very bright green, with white margins to the feathers; and there is also a band of small silky feathers of a bright green colour, that extends from the lower mandible at the gape to the eyes, and these feathers have white margins as well as those of the crest. The nape, the upper part of the neck, and the breast are also bright green, with white margins to the feathers. The coverts of the wings are iridescent green, and the quills black. The under parts, the belly and the under tail-coverts are brownish fawn colour; the bill black, and the naked parts on the sides of the neck and the appendage to the throat are very clear bright red, thinly scattered over with black hairs. The feet are reddish and the claws black. It is smaller than the other species, being only about twenty-six inches in length when full grown. The colours of the female are less brilliant than those of the male, and her whole plumage has a slight reddish tinge. The young in

the early stage are covered all over with downy feathers of a russet colour.

According to Sonnini this species of guan is very easily tamed, and so familiar in a state of domestication, as to be absolutely troublesome. It soon knows those people who are about it and kind to it; and it is so fond of being caressed that it runs about their feet, and is in danger of getting trampled on, or tumbling them down in their attempts to avoid it. It utters cries of persuasion similar to those uttered by a common hen when she collects her chickens. When in a state of nature it is a quiet and gentle bird, frequenting solitary places, and feeding chiefly upon wild fruits. In their general habits they almost constantly perch upon trees, though they feed on the ground. Their short and hollow wings are ill adapted for forward flight, which they make with even more labour and noise than a common barn door fowl; but they leap to their perches or from them with considerable ease and agility, and they run very swiftly, making use of their half expanded wings to row them along, as is the case with ostriches. In many of their habits they approach more nearly to the jungle fowl of India than to any other of the native gallinidæ of South America. In many of their habits, as well as in their generic characters, they differ from these. The males are monogamous, and show no disposition to fight or quarrel with each other, or indeed with any other creature. They live generally in pairs, and shun the society not only of all other birds, but of each other, except the pair and the family during the first year. The female makes her nest in trees, and the eggs vary from two to five. In the morning they are very early birds, and their cry is heard as the dawn is breaking; but though loud it is hoarse and disagreeable. During the day, however, they are seldom heard, and in their native haunts in the forests, they are very seldom seen.

The hoarse voice of this species appears to arise from the convolutions of the trachea, which are somewhat different from those of the crested guan, and approximate more to the wood-grouse and the spoon-bill: the texture of the organ is nearly the same in both, being composed of rings alternating with membranous partitions; it ascends along the neck as far as the union of the coracoid bones, then it passes into the interior on the left side of the gizzard, returns in front of the left coracoid, as far as the furcal bone, at its union with the sternum, where it returns back again and proceeds to the lungs. The anterior part, which extends forwards, has a peculiar muscle attached to it, by which it is secured to the crest of the sternum and also to the pectoral muscles.

Though the number of eggs in this species is less than that of some of the others, they hatch twice in the year, in December or January, when the rainy season commences, and in May or June, when it is over. The nests are carefully concealed in thick bushes; and, different from many of the gallinidæ, the mother feeds them for some time in the nest. This lasts for about two weeks, by which time their feathers have begun to sprout; and the mother descends with them, and tends and feeds them on the ground, until they are so far fledged as to be able to perch. Their first food consists of insects, small seeds, and fruits, for which the parent bird scrapes the ground in the same manner as the common hen; she also calls them to her by similar cries, and gathers them under her wings for

shelter or protection. The young are very easily tamed, and they readily find their way back to a home in which they have been fed and otherwise kindly treated; but they are not fond of passing the night within doors, preferring a perch on trees, if there are any in the neighbourhood.

**THE PARRAQUA** (*Ortalia*). This genus has been confounded both with the former and with the true pheasants; but its characters are sufficiently distinct from both. They are very noisy birds, and the name parraqua is nearly expressive of their cry: with the true pheasants this bird has few characters in common, and it is easily distinguished from the genus *Penelope*. The culmen of the bill is more elevated and curved, and the tip more enlarged and arched. There are no elongated naked appendages to the throat, and very little naked skin, only a narrow band extending downward from each corner of the gape; the space between these stripes is covered with black skin, not feathered but beset with hairs. The upper parts are mottled with grey, green, and red; the front, the top of the head and the upper part of the neck are deep red; the coverts of the wings are red, with the exception of six of the middle ones, which are iridescent green, and the quills are of the same colour, but not so brilliant. The lower part of the neck and the breast are olive grey; the bill black but greyish at the tip; a bluish circle of naked skin around the eyes, and the feet reddish; the length is about twenty-two inches. The young are smaller in size, and have the red spots on the upper parts more conspicuous, while the under part is brownish, with grey margins to the feathers. These birds construct their nests on small and tufted branches, at about seven or eight feet from the ground; they lay from four to six eggs. When the young are disclosed they descend in a short time from the nest, and the mother conducts them in a similar manner to the common hen. The usual aliments of these birds vary very much; but when young, and having just quitted the nest, their food principally consists of worms and small insects, which the mother procures for them by scratching up the earth: they quite abandon the mother when they are grown large and are able to fly. Besides fruits, seeds, and in all probability, insects, these birds occasionally feed upon the young and tender grass, with which the savannahs begin to be covered after they have been watered by the rains. The feeding time is early in the morning, before the heat of the sun becomes strong; for after that they retire to the shelter of the woods, and as they seek the cover of the very thickest foliage, it is with difficulty that they can be seen during the day; but in the evening, when it begins again to get cool, they come out of their hiding-places, and utter their loud and harsh cries: they feed a second time in the evening, and when light fails them, they return to their perches in the trees. They are found in the western valleys of the Colombian states, as well as in the valleys of the larger rivers further to the east and south. Humboldt in his travels among the ridges of the Northern Andes and their spurs, found them in the deep and romantic valley of the Magdalena, perched in flocks of sixty or eighty upon the withered trees, and making the neighbourhood to resound with their harsh and piercing cries.

The trachea of the parraqua is more convoluted than that of the crested or the marail guan: it passes over the left coracoid nearly the entire height of the

great pectoral muscle, doubles back nearly the length of this muscle along the external surface of the peritoneum, and is reflected forward, divides, turns backward, and proceeds to the lungs. Humboldt measured the length of this tube both in the male and the female; and the difference is so great, that were the fact not known to be otherwise, they might be taken for different species. The difference of the bodies of the birds is not more than an inch or two in length; but the convoluted trachea of the male is nearly three times as long as the unconvoluted trachea of the female; the former measuring fifteen inches and a half, and the latter only five and a half.

**HOAZIN** (*Opisthocomus*). This is a bird of the same countries with the *Alectoridæ*, but it unquestionably belongs to a different family. Doubts were at one time entertained as to its existence; and now that the fact of there actually being such a bird is well established, its place in the system has become a little puzzling. It was first described by Fernandez as a Mexican bird, about the same size as a turkey, standing higher than the curassow, and of a different form and air: it was described as having a tufted crest of feathers, white on the one side, and black on the other, a curved bill, the breast yellowish white, and the wings and tail marked with dark spots and stripes: the back, the neck, and sides of the head of a rusty brown colour, and the feet dull raven grey. The same writer added, that its voice, which bears some resemblance to the sound of its name, is very powerful, and resembles something between a croak and a howl: he adds that it inhabits the deep forests, and perches upon trees near the banks of the waters, waiting for serpents, which constitute the chief part of its prey: the same author mentions a smaller bird somewhat similar, but feeding differently, and eatable, though by no means delicious; the other being altogether unfit for this purpose. It does not appear that there is much truth in any of these statements; and it is probable that Fernandez confounded together two birds of very different species, the one an aquatic fishing bird, and the other some such bird as the one under consideration, though very imperfectly known to the describer. Later writers have been induced to class this genus with the omnivorous birds; but it does not appear, at least from any thing that is known, that it partakes much of this character. There is, however, only a shade of difference between some of the omnivorous birds and some of the gallinidæ; for of the former some are easily tamed, and of the latter not a few are very miscellaneous in their feeding: it is probable that when this bird comes to be better known it may be found to require a distinct place.

The generic characters are, the bill short and stout, convex in the culmen, curved and compressed laterally towards the tip, but enlarged at the sides towards the base, and with the lower mandible strong and angular at the point. The nostrils are placed in the middle of the surface of the bill, and partially covered above with a membrane; the feet are stout and muscular, with short tarsi, and four toes, entirely divided to their bases, and with the two lateral ones unequal, and all bordered with rudimental membranes: the middle toe is as long as the tarsus or longer, the wings are of mean length, concave and rounded, the first quill being very short, the next four increasing by regular stages, the sixth being longest in the wing: the tuft on the head is composed of narrow feathers, which are red in the basal half, and black in the distal

When the bird is in a state of repose they hang down as far as the middle of the neck; but when it is excited it can raise them so that they stand out from the hind head. At the same time it expands the tail in a fan-shape, and, in fact, it has some of the air and gait of the peacock, but differs much in colour.

There is only one known species, the *sasa* of Sonnini, the "crested pheasant" of Latham, and *Opisthocorvus cristatus* of Illiger, the last of which names is retained by Cuvier, who remarks justly that Vieillot gives a very inaccurate representation. The upper parts are of a blackish-brown colour: the top of the head is reddish, furnished with a crest of feathers, coloured as already noticed: the back of the neck is blackish, with a white line on the shaft of each feather: the larger and middle coverts of the wings have white tips, the lesser coverts have their exterior webs white, and their interior brown: the first four quills of the wings are wine-red with brown points; those next them are bordered with brown in their outer webs, and those next the body are altogether blackish-brown: the tail-feathers are greenish-black with white tips: the chin is brown, the lower part of the neck and the breast are reddish-white, the rest of the under parts wine-red, and the bill and feet brown: the length is about twenty inches.

The manners of this species are unknown; and it should seem that the birds themselves are not very abundant. Sonnini mentions that there are but few in number in those parts of Guiana through which he travelled. Occasionally he has met them in small flocks, not exceeding six or eight in number. He never found them in the deep woods or in elevated situations; but on the inundated savannahs and other marshy places, where he did not observe them on the ground, but on the leaves of the arborescent arum (*Arum arborescens* of Linneus), which grows to the height of five or six feet, and is very plentiful in the marshes of the tropical countries. It is on the succulent berries of this arum that these birds are described as having been chiefly seen feeding. This is a little singular, and shows that there is a consumer provided for almost every substance. The milky juice of this arum is of so acrid a nature as to blister the hands of those who touch it; and yet, according to the accounts, these birds make the plant their constant habitation and their regular food, eating the leaves and flowers at those times when there is no fruit upon it. The same author, to whom we are indebted for the only exact description of the bird, whether it be or be not the hoazin of Fernandez, further mentions that they are always found perched on the trees in the marshes, and that they repose in pairs close to each other. Their voices are loud and harsh, and bear so much resemblance to the word *sasa*, that the natives of Guiana know them by that name. In the same trees, or rather arborescent plants, they form their nests, externally of small branches, and internally lined with down; the last of which is certainly not a custom with any of the common gallinaceous birds. The hatch consists of five or six eggs; but the state of the young has not been very particularly examined. The flesh of these birds has so strong a flavour of musk as not to be at all relished by Europeans, and we believe that it is not much, if at all, eaten by the natives. It is worthy of remark, that in this musky flavour it agrees with the flesh of the mammalia and reptiles which inhabit the waters of tropical America and their borders.

The genera of which we have now given some slight account, but respecting many of which more accurate information would be highly desirable, comprehend nearly the whole of the gallinaceous birds which are found only in the tropical parts of the American continent. With very few exceptions, and those apparently exceptions of mere variety, they are all larger than the races of the same order which inhabit the southern parts of the eastern continent. Their plumage is also of a more sombre character, though, in many of the species, the glosses, and even the tints, are exceedingly rich. The appendages to their heads and necks will also be observed to be peculiar, and more unlike what we are accustomed to in the native birds of Europe, than any thing which occurs in the genera of the south and the east. We may also add that, taking them as a whole, their manners are much more gloomy; they have not the same briskness and spirit, and their flesh is very inferior in an economical point of view.

There is still one genus which, though it resembles the quails in some particulars, and is included by Cuvier in the grouse family (*Tetraonidæ*), may be mentioned here for the sake of including in one arbitrary division the same geographical locality. This species is

**TINAMOUS** (*Crypturus*). The characters of this genus are: the bill straight, slender, depressed, broader than high, and blunt, and rounded at the extremity. The upper mandible enlarged on the upper part, and margined at the tip. The nostrils placed in the middle of the bill, in long nasal grooves, oval in their shape, and open. The legs are rather long, and the tarsi are often furnished with hard tubercles on the hinder edges. There are four toes, entirely divided, all of them rather short, and the hind toe reaching the ground in some species, but not in others. The claws on the toes are small and flattened. The wings are short and rounded; the first four feathers increase in length by regular stages; and the fifth and eighth are the longest in the wing. The tail consists of ten feathers. It is short in all the species, and merely rudimental in some of them, on which account the name *crypturus*, "obscure tail," is applied to the genus.

It will easily be inferred from the characters which we have described, that those birds are very different in their habits from the other gallinidæ of the warmer regions of America. The shortness and roundness of their wings render them incapable of long flights, and the shortness of the tail or the want of it unfits them for ascending and descending with the same ease as the perching birds, which, whatever may be the character of their wings, always have the tail well formed. Their structure points out their peculiar habitat, which is the wide and extended plains, or the margins of the forests, but not the forests themselves. They are found as far north as Mexico; and also in Guiana, but they are much more numerous in Brazil, and in the plains of Paraguay. There they are found in vast numbers, living and multiplying much in the same manner as partridges; though, as the physical circumstances of their native country are different from those of many of the places which partridges inhabit, we may expect corresponding differences in their structure. Accordingly they run with much greater swiftness than any of the partridge tribe, so that in their speed they bear some resemblance to little ostriches; and in the course of the

year they range over no inconsiderable extent of surface. This becomes necessary; for during the latter part of the dry season the produce of their pastures is exhausted, and during the rains a considerable extent of those pastures is laid under water. Neither the one nor the other of those circumstances occurs in the same district at the same time; so that the birds have a sort of seasonal movement between the higher and the lower grounds. From their being obliged to walk more vigorously and migrate further than the partridges of the eastern continent, the flesh of the old birds is not so tender as that of partridges. Still, however, they are much esteemed, and eagerly hunted by the *guassows* or peasantry of South America. They are naturally unsuspicious, and not afraid of the hunters, who thus procure them in great numbers. They indeed disperse themselves during the day; but they assemble in flocks during the night. They form their nests of dry leaves under the bushes, in a very rude manner; and some idea of their fertility may be formed, when it is stated that they breed twice in the year, and have from fifteen to twenty in a hatch. They eat all manner of seeds, small fruits, berries, and insects; but though they often resort to the woods and copes in search of these, they do not perch or pull them from the bush, as they pick them up from the ground, that being their proper feeding place; and they scrape the earth in the same manner as poultry. The soil, in such a country as South America, affords a rich pasture for *rasorial*, or scraping birds, because the heavy rains beat down a number of seeds and other matters, and so incorporate them with the soil, that they require to be scraped out. Altogether, though there is a resemblance between this genus of birds and the partridges, both in form and in use in the economy of nature, yet it is impossible to help admiring the beauty and perfection with which each is adapted to her peculiar diversity, and suited to the peculiar physical character of its own country. Nor is it unworthy of remark, that the small mammalia which inhabit nearly the same places of South America, as the tinamous, are also all feeders on the ground, and the greater number of them are burrowing animals, which scrape the earth not merely for the purpose of forming habitations, but for that of finding them food, at least at certain seasons. The reader who wishes to see more of this analogy between the ground birds and the ground mammalia of the dry plains of South America, may compare what has been now said with what will be found noticed in the articles ARMADILLO and CHINCHILLIDÆ, in their places in the alphabet in a former part of this work. There are a good many species of this genus, of which we shall give some short notice:—

*Crypturus magoua*. This species has been called Brazilian; but it occurs in perhaps equal abundance in other parts of South America. The ground colour all over is olive-brown, slightly striated across, with black above, greyish red beneath; crown rufous; the secondary quills transversely striated with rufous and black. Size of a common fowl. About eighteen inches in length; the body more compact and thicker than that of the pheasant. The birds of this species inhabit Brazil and French Guiana, where they roost on the low branches of trees, two or three feet from the ground. The female lays from twelve to fifteen eggs, of the size of those of a hen, and of a beautiful green colour, in a nest formed on

the ground, among the thick herbage, and carelessly composed of moss and dried vegetables. The young run, almost as soon as they are hatched, after the mother, and hide themselves on the least appearance of danger. Their cry, which is a sort of dull whistle, may be heard a great way off. Many of them are shot, and many caught, when roosting on the trees. The flesh and eggs are esteemed great dainties.

*Crypturus rufescens*, the reddish tinamou, called also the *guazu*, has the ground colour greyish red, transversely, striped with black and white above, margin of the wings rusty red; region of the ears black, breast pale yellowish red, waved with brown beneath. Sides and abdomen greyish. Fifteen inches and a half in length. This bird is a native of Paraguay, and the most beautiful of its family residing among thick herbage, which it seldom quits, except on the point of being trampled on or struck with a stone. Its cry, which is heard at a considerable distance, is a lugubrious whistle. The female conceals her rude nest among dry stalks, in a tuft of grass or under a bush, and the eggs are said to be not quite so numerous as those of the former species. The eggs are of a delicate violet colour, and of nearly equal thickness at both ends. When these birds are alarmed they erect the feathers on the head, something in the form of a crest. They are found in Brazil as well as in Paraguay.

*Crypturus nanus*, is a small species found also in Brazil and Paraguay. The upper parts are of a brownish colour, with the extremities of the feathers on the back and rump black, and beautifully waved with greyish white. These last feathers are, in some specimens, very much enlarged, and have reddish spots of red between the black ones. The top of the head is mottled with red and grey, with the middle of the feathers black; the cheeks and sides of the neck are greyish ash colour, with black borders to their feathers. The nape and upper part of the nape brownish ash with black centres. The small and middle coverts are reddish cream colour, rayed with black, and with large white spots; the quills black, with rust-coloured borders to their outer webs; the throat and middle of the under part are whitish, with obscure black streaks; the breast is cream-yellow, streaked with brown; the feathers on the rump are loose and downy, and form a sort of silky tuft; the bill is brown, with the base of the lower mandible yellow, and the feet are yellow. The full grown male of this interesting little species is only about six inches in length. The female is an inch shorter; the colours incline more to red, and the black spots on the upper part are not nearly so conspicuous.

*Crypturus obsoletus* is another species found in the same localities with the last-mentioned; but it is larger in size. The upper parts are blackish-brown, clouded with red; the top of the head and the upper part of the neck blackish-ash; the sides of the neck and the throat reddish-ash; the back of the neck, the breast, the flanks, and the belly, are bright rust-coloured red; and the feathers on the flanks and belly are produced so as to clothe the thighs; their ground colour is rust-red, and they are strongly rayed with black. The feathers of the tail are exceedingly short, and entirely hidden by the coverts. The bill and feet reddish-brown. The length of the full grown male is about eleven inches and a half. The female is smaller and duller in the colours. This is described as a very swift-footed species.

*Crypturus noctivagus*. This is a Brazilian species, and gets its name from its habit of stirring and uttering its cry during the night, or, at all events, very early in the morning and very late in the evening. The upper part is dull greyish ash, clouded with brown and reddish and streaked with black. The top of the head and the rump are rusty brown, and the coverts blackish brown. The throat is whitish, the breast pale rose colour, and all the rest of the under part russet. The bill brown, with the base of the under mandible whitish and the feet brownish ash. The full grown male is between thirteen and fourteen inches in length.

There are about as many more known species as those which we have mentioned; and it is probable that there are several others which have hitherto escaped observation; but none of them appear to differ so much from each other as that a further enumeration would be interesting to the general reader. The vast number of species, however, and the fact of the whole of these species being confined to the American continent southward of the isthmus of Darien, are worthy of notice, as indicating the peculiar state of nature in the greater number of her productions in that part of the world. They are indeed so unique, so different from those of other countries, even from those of Africa, Holland, and the eastern islands which have the same latitude, that they especially recommend themselves to every one who wishes to study the relations which subsist between a country considered in its structure and meteorology, and the organised beings, whether animal or vegetable, which that country produces.

We have next to mention an American genus, which, in an economical point of view, and for the purposes of domestication, is certainly more valuable, upon the whole, than any other, except common poultry, and, in the individual bird, far more valuable than even these. If we except the potato, this bird must be regarded as by far the most valuable natural production of the American continent which has been introduced, and, to a great extent, naturalised in Europe. We need hardly say that we allude to

*MELEAGRIS*, the turkey; neither need we give any long description of the external appearance of a bird of which there is but one species, that species generally known, and more rarely breaking into varieties than any other with which we are acquainted.

The generic characters are: the bill short and thick; the head and upper part of the neck covered with a naked skin, beset with tubercles; the throat furnished with a longitudinal pendulous and knobby wattle, which is partially covered with hairs. There is also a conical fleshy knob, thinly scattered with hairs on the tip, and it arises from the junction of the bill with the forehead. When the bird is in a state of repose, and not disturbed nor alarmed, this appendage is short; and when the bird is strongly excited, it enlarges till it covers the whole bill, and hangs two or three inches over its tip. The neck is of moderate dimensions, both as to length and to thickness; and to the lower portion of it there is attached an appendage of a fleshy texture, furnished at the end with a brush of hard black hairs, about nine inches long.

There is, as we have said, but one species, the common turkey (*Meleagris gallo-pavo*), which is a favourite bird in our farm yards, though much inferior to what it is in a state of nature; and, indeed, those

who have seen only the domestic bird in Europe, even in those places where it seems to thrive best, can have no idea of the splendour of its appearance in a state of nature. The male is then, when full grown, little less than four feet in length, and at least five in the extent of the wings. The body is thick, rather lengthened, and covered with feathers, which are very abrupt at their terminations. The webs of these feathers at the basal part consist of sooty-coloured down, beyond which they are dusky, and terminate in a broad band of rich metallic lustre, the colours of which are very varied when the light falls variously upon them—changing from bright golden colour, through different shades of copper, bronze, violet, and purple. On the back the feathers have, beyond this, a terminal band of velvet black, without any reflections. The metallic glosses are richest on the upper parts of the back, and the black deepens towards the rump and tail-coverts, though on the latter there is a broad band of bright coppery lustre, and a slight bay margin beyond the velvet band; and the last ones have more of the bay colour, crossed with narrow bars of metallic green. The feathers on much of the under part are dark, and glossed with reflections, but of less intensity than those on the back. The wings are hollow and rounded, and do not reach beyond the insertion of the tail. They consist of twenty-eight quills each, of which the first is very short, and the fourth and fifth the longest in the wing. The coverts next the scapulars are like the feathers on the body; those next the quills are copper and violet, beyond which there is a black band and a whitish tip. The bastard wing, the coverts of the primaries, and the primaries themselves, are blackish, banded with white; the second are white, banded with black, but with a trace of rusty yellow, which increases on the tertiary quills, and is there marked with some metallic reflections. The tail is composed of eighteen hard and strong feathers, of a rust colour, mottled with black, crossed by narrow lines of the same colour, and with a broad black bar nearly at the tips. These tail-feathers are very strong, and more than fifteen inches in length in the full grown bird when in a state of nature; so that when the tail is spread out like a fan, as the bird is excited, and parades, struts, and wheels about, the tail, though it wants the rich tints and light and airy spread, like that of the peacock, is far from being destitute of grandeur. The legs and feet are very stout and rather long, the tarsi measuring about six inches. They are covered with imbricated scales of a five-sided shape, and have a strong and compressed, but rather blunt, pointed spur on the insides. The three front toes are connected at the base by a membrane, the middle one being about four inches in length, each of the lateral ones about two inches, and the hind toe, which touches the ground only with its tip, is about one inch in length. The female is considerably smaller; and the head and neck are covered by irregular feathers of a dull grey colour. The feathers on the back have the tips rusty; the tubercle over the bill is merely rudimental, and the tuft on the lower part of the neck is generally wanting altogether. There is, however, a concealed rudiment of it, and when the females become barren, which is said to be pretty frequently the case with the wild birds, this appendage makes its appearance, though it is always much more slender than in the males. The hunters who are engaged in the capture of wild

turkeys learn to distinguish such birds, and select them with great care, as they are reckoned finer food than either the males or the fertile females. At one season of the year, generally about the month of March, both of these, and more especially the males, become so lean, that they are hardly fit for the table, while, at this season, the barren females are understood to remain in as prime condition as at any other. What proportion these barren females, which there is some reason to suppose are more numerous in this genus than in any of the others, may bear to the total number of the birds, has not been ascertained; but it would almost appear as though a natural provision were made in this race of a surplus for human food, in the same manner as a similar surplus is often obtained by artificial mutilation in domestic poultry, and in some other animals.

When America was first discovered, the wild turkey was found in abundance along the whole range from Canada to near the isthmus of Darien, though it does not appear ever to have been met with further to the south; and even in Mexico it was less plentiful, and of inferior quality, clearly indicating that its true home is in the temperate latitudes. The absurd name of "turkey" is given to it only in England; and it originated in the time of Henry VIII., when every thing of foreign production which was highly esteemed, had the same epithet given to it. It even found its way into the Latin dictionaries, as *Gallus Numidicus*, as if it had come from the north of Africa; and so prevalent was the error that the eminent naturalist Ray, and after him the honourable Daines Barrington, described it as a native of Africa, and the tropical parts of Asia, whereas it is not found in either of these quarters of the world, neither is it a tropical bird.

The settlers in North America, appear to have been much more intent upon killing the wild turkeys, and cutting down their favourite forests, than in attending to their natural history, or inquiring whether they might not have been profitably preserved in a country which, like the United States, must continue, comparatively at least, thinly peopled for ages.

It is now rare in the southern states, Florida, Georgia, and the Carolinas; very rare in the states of the centre of the Union; and in the north-east it has been extinct for a century and a half. The western states on the Mississippi, and its affluents, where the woods are still remaining, are now the head quarters of these birds in a state of nature; and it is not supposed that the birds are at all known in the elevated parts of the Rocky Mountains or the country beyond. We shall here make an extract of the account of their manners in the wild state, as given by, or rather to, Prince Charles Lucien Buonaparte, as it is the most circumstantial that has appeared, and as the turkey is known with us only as a domestic, and, in fact, as a degenerate bird.

"The wild turkeys," say these describers, "do not confine themselves to any particular kind of food; they eat maize, all sorts of berries, fruits, grasses, beetles, and even tadpoles; young frogs, and lizards, are occasionally found in their crops; but when the pecan nut is plenty, they prefer that fruit to any other nourishment; their more general predilection is, however, for the acorn, on which they rapidly fatten. When an unusually profuse crop of acorns is produced in a particular section of country, great numbers of turkeys are enticed from their ordinary haunts in the

surrounding districts. About the beginning of October, while the mast still remains on the trees, they assemble in flocks, and direct their course to the rich bottom lands. At this season they are observed in great numbers on the Ohio and Mississippi. The time of this irruption is known to the Indians by the name of the *turkey month*.

"The males, usually termed *gobblers*, associate in parties, numbering from ten to a hundred, and seek their food apart from the females; whilst the latter either move about singly with their young, then nearly two-thirds grown, or, in company with other females and their families, form troops, sometimes consisting of seventy or eighty individuals, all of whom are intent on avoiding the old males, who, whenever opportunity offers, attack and destroy the young, by repeated blows on the skull. All parties, however, travel in the same direction, and on foot, unless they are compelled to seek their individual safety by flying from the hunter's dog, or their march is impeded by a large river. When about to cross a river, they select the highest eminences, that their flight may be the more certain; and here they sometimes remain for a day or more, as if for the purpose of consultation, or to be duly prepared for so hazardous a voyage. During this time the males gobble obstreperously, and strut with extraordinary importance, as if they would animate their companions, and inspire them with the utmost degree of hardihood; the females and young also assume much of the pompous air of the males, the former spreading their tails, and moving silently around. At length the assembled multitude mount to the tops of the highest trees, whence, at a signal note from a leader, the whole together wing their way towards the opposite shore. All the old and fat ones cross without difficulty, even when the river exceeds a mile in width; but the young, meagre, and weak, frequently fall short of the desired landing, and are forced to swim for their lives; this they do dexterously enough, spreading their tails for a support, closing their wings to the body, stretching the neck forwards, and striking out quickly and forcibly with their legs. If, in thus endeavouring to regain the land, they approach an elevated or inaccessible bank, their exertions are remitted, they resign themselves to the stream for a short time, in order to gain strength, and then with one violent effort escape from the water. But in this attempt, all are not successful; some of the weaker, as they cannot rise sufficiently high in air to clear the bank, fall again and again into the water, and thus miserably perish. Immediately after the turkeys have succeeded in crossing a river, they for some time ramble about without any apparent unanimity of purpose, and a great many are destroyed by the hunters although they are then least valuable.

"When the turkeys have arrived in their land of abundance, they disperse in small flocks, composed of individuals of all sexes and ages intermingled, who devour all the mast as they advance: this occurs about the middle of November. It has been observed, that, after these long journeys, the turkeys become so familiar as to venture on the plantations, and even approach so near the farm-houses, as to enter the stables and corn cribs in search of food; in this way they pass the autumn, and part of the winter. During this season great numbers are killed by the inhabitants, who preserve them in a frozen state, in order to transport them to a distant market. Early in March they begin to pair; and, for a short time previous, the females

separate from, and shun their mates, though the latter pertinaciously follow them, uttering their gobbling note. The sexes roost apart, but at no great distance, so that, when the female utters a call, every male within hearing responds, rolling note after note, in the most rapid succession; not as when spreading the tail and strutting near the hen, but in a voice resembling that of the tame turkey, when he hears any unusual or frequently repeated noise: when the turkeys are numerous, the woods from one end to another, sometimes for hundreds of miles, resound with this remarkable voice of their wooing, uttered responsively from their roosting-places. This is continued for about an hour; and, on the rising of the sun, they instantly descend from their perches, and the males begin to strut, for the purpose of winning the admiration of their mates.

"If the call be given from the ground, the males in the vicinity fly towards the individual, and, whether they perceive her or not, erect and spread their tails, throw the head backwards, distend the comb and wattles, strut pompously, and rustle their wings and body feathers, at the same moment ejecting a puff of air from the lungs. Whilst thus occupied, they occasionally halt to look out for the female, and then resume their strutting and puffing, moving with as much rapidity as the nature of their gait will admit. During this ceremonious approach, the males often encounter each other, and desperate battles ensue, when the conflict is only terminated by the flight or death of the vanquished. This pugnacious disposition is not to be regarded as accidental, but resulting from a wise and excellent law of nature, that always studies the good of the species, without regard to the individuals. Did not females prefer the most perfect of their species, and were not the favours of beauty most willingly dispensed to the victorious, feebleness and degeneracy would soon mark the animal creation; but, in consequence of this general rule, the various races of animals are propagated by those individuals who are not only most to be admired for external appearance, but most to be valued for their intrinsic spirit and energy.

"When the object of his pursuit is discovered, if the female be more than one year old, she also struts, and even gobbles; she turns proudly round the strutting male, and suddenly opening her wings, throws herself towards him, as if to terminate his procrastination. But should he meet a young hen, his strut becomes different, and his movements are violently rapid; sometimes rising in air, he takes a short circular flight, and on alighting, drags his wings for a distance of eight or ten paces, running at full speed, occasionally approaching the timorous hen, and pressing her until she yields to his solicitations. Thus are they mated for the season, though the male does not confine himself exclusively to one female, nor does he hesitate to bestow his attentions and endearments on several, whenever an opportunity offers.

"One or more females, thus associated, follow their favourite, and roost in his immediate neighbourhood, if not on the same tree, until they begin to lay, when they change their mode of life in order to save their eggs, which the male uniformly breaks if in his power, that the female may not be withdrawn from the gratification of his desires. At this time the females shun the males during the greater part of the day; the latter become clumsy and careless, meet each other

peacefully, and so entirely cease to gobble that the hens are obliged to court their advances, calling loudly and almost continually for them. The female may then be observed caressing the male, and imitating his peculiar gestures.

The cocks, even when on the roost, sometimes strut and gobble, but more generally merely elevate the tail, and utter the puff, on which the tail and other feathers suddenly subside. On light or moonshining nights, near the termination of the breeding season, they repeat this action, at intervals of a few minutes, for several hours together, without rising from their perches. The sexes then separate; the males, being much emaciated, cease entirely to gobble, retire and conceal themselves by prostrate trees, in secluded parts of the forest, or in the almost impenetrable privacy of a canebrake. Rather than leave their hiding-places, they suffer themselves to be approached within a short distance, when they seek safety in their speed of foot; at this season, however, they are of no value to the hunter, being meagre and covered with ticks. By thus retiring, using very little exercise, and feeding on peculiar grasses, they recover their flesh and strength; and when this object is attained, again congregate, and recommence their rambles.

"About the middle of April, when the weather is dry, the female selects a proper place in which to deposit her eggs, secured from the encroachment of water, and, as far as possible, concealed from the watchful eye of the crow: this crafty bird spies the hen going to her nest, and, having discovered the precious deposit, waits for the absence of the parent, and removes every one of the eggs from the spot that he may devour them at leisure. The nest is placed on the ground either on a dry ridge, in the fallen top of a dead leafy tree, under a thicket of sumach or briars, or by the side of a log; it is of a very simple structure, being composed of a few dried leaves. In this receptacle the eggs are deposited, sometimes to the number of twenty, but more usually from nine to sixteen; they are whitish, spotted with reddish brown, like that of the domestic bird. Their manner of building, number of eggs, period of incubation, &c., appear to correspond throughout the Union, as I have received exactly similar accounts from the northern limits of the turkey range to the most southern regions of Florida, Louisiana, and the western wilds of Missouri. The female always approaches her nest with great caution, varying her course so as rarely to reach it twice by the same route; and on leaving her charge, she is very careful to cover the whole with dry leaves, with which she conceals it so artfully as to make it extremely difficult, even for one who has watched her movements, to indicate the exact spot; hence few nests are found, and these are generally discovered by fortuitously starting the female from them, or by the appearance of broken shells, scattered around by some cunning lynx, fox, or crow. When laying or sitting, the turkey hen is not easily driven from her post by the approach of apparent danger; but if an enemy appears, she crouches as low as possible, and suffers it to pass. A circumstance, related by Mr. Audubon, will show how much intelligence they display on such occasions: having discovered a sitting hen, he remarked that, by assuming a careless air, whistling, or talking to himself, he was permitted to pass within five or six feet of her; but if he advanced cautiously, she would not suffer him to come

within twenty paces, but ran off twenty or thirty yards with her tail expanded, when, assuming a stately gait, she paused on every step, occasionally uttering a chuck. They seldom abandon their nests on account of being discovered by a man, but should a snake, or any other animal, suck one of the eggs, the parent leaves them altogether. If the eggs be removed, she again seeks the male and recommences laying, though otherwise she lays but one nest of eggs during the season. Several turkey hens sometimes associate, perhaps for mutual safety, deposit their eggs in the same nest, and rear their broods together.

"When the process of incubation is ended, and the mother is about to retire from the nest with her young brood, she shakes herself violently, picks and adjusts the feathers about the belly, and assumes a different aspect; her eyes are alternately inclined obliquely upwards and sideways; she stretches forth her neck, in every direction, to discover birds of prey or other enemies; her wings are partially spread, and she softly chucks to keep her tender offspring close to her side. They proceed slowly, and, as the hatching generally occurs in the afternoon, they sometimes return to pass the first night in the nest. While very young, the mother leads them to elevated dry places, as if aware that humidity during the first few days of their life would be very dangerous to them, they having then no other protection than a delicate, soft, hairy down. In very rainy seasons wild turkeys are scarce, because, when completely wetted, the young rarely survive. At the expiration of about two weeks the young leave the ground on which they had previously reposed at night under the female, and follow her to some low large branch of a tree, where they nestle under the broadly curved wings of their vigilant and fostering parent. The time then approaches in which they seek the open ground or prairie land, during the day, in search of strawberries and subsequently of dewberries, blackberries, and grasshoppers; thus securing a plentiful food, and enjoying the influence of the genial sun. They frequently dust themselves in shallow cavities of the soil or on anthills, in order to clean off the loose skin of their growing feathers, and rid themselves of ticks and other vermin. The young turkeys now grow rapidly, and in the month of August, when several broods flock together, and are led by their mothers to the forest, they are stout and quite able to secure themselves from the unexpected attacks of wolves, foxes, lynxes, and even cougars, by rising quickly from the ground, aided by their strong legs, and reaching with ease the upper limbs of the tallest tree. Amongst the numerous enemies of the wild turkey, the most dreaded are the large diurnal and nocturnal birds of prey, and the lynx (*Felis rufa*), who sucks their eggs, and is extremely expert at seizing both parent and young: he follows them for some distance in order to ascertain their course, and then, making a rapid circular movement, places himself in ambush before them, and waits until, by a single bound, he can fasten on his victim."

As already mentioned, the turkey was introduced into England in the early part of the sixteenth century. It came first from Mexico to Spain, and then from Spain to England in 1524, and it soon spread over the other countries of Europe, at first as curiosities, but afterwards as articles of food. Who was the first to feed on a turkey in the British islands has

not been recorded, but in France it was first served up at the nuptial feast of Charles IX. in 1570, about forty years after its first introduction into that country. It is probable that by this time the numbers had considerably augmented; and, though the fact is not established by evidence, it is probable that the general stock of European turkeys are from those that came from Mexico, and their being inferior in Mexico to what they are in North America, that is in the valley of the Mississippi, may in part account for the decided inferiority of the European ones, which applies to quality, and still more to weight. Wild turkeys, weighing between twenty and thirty pounds, are mentioned as not being unfrequent; while we believe those of Europe do not exceed the half of that weight.

It is worthy of remark, as showing the general difference between the physical condition of the two continents, and the adaptation of its own natural productions to each, that, while the cock of the Indian jungles, and the pheasants and other gallinidæ of the warmer countries of south-eastern Asia, which have been introduced into our climates, have not deteriorated it, but have been improved by care, at least in some of the species, the turkey, which is a native of temperate climates in America, and even of climates which have their winter as severe as it is in Lapland, should not have stood the change so well. It seems, however, that the turkey is more a bird of wild nature than the gallinidæ of the south-east; for even in the United States those which are kept in a domesticated state are inferior to the wild ones, both in size and in beauty of plumage. In some parts of that country, where wild ones are still to be met with in the neighbourhood, we believe it is customary to improve the breed by procuring the eggs of the wild ones, and hatching them under the domestic; and as a turkey hen may, by proper management, be made to continue sitting until she has hatched two broods or even three, one hen may, if the eggs can be procured, hatch a number of those half wild ones in the course of one season, if they are removed and reared by hand as soon as they are hatched.

In this country the rearing of turkeys requires more care than that of any other bird in the poultry yard; and some attention is necessary in order to preserve the eggs. In Europe these are laid in the spring, and are generally from fourteen to eighteen in number; white is the general colour, but freckled with yellow and reddish. The hens naturally seek obscure places, where their eggs may be safe from the male bird, as he is very prone to destroy them. The hen also is sometimes known to destroy her own eggs, although in general she is a very persevering sitter. It appears, however, from various accounts, and among the rest, from an anecdote related in the Memoirs of the Academy of Stockholm, that the cock turkey is not incapable of performing the duties of a nurse. M. Carlson remarks on this occasion, that the total neglect of their young, ascribed to male birds that associate with a plurality of females, is not general. Geese are of this description, and yet the gander protects the young with the greatest care. But the instance of a turkey cock sitting on eggs seems the more singular, because both in a wild and tame state the males are accustomed to destroy the nests of the females, in order that they may have them sooner free for pairing; and, for this reason, the cock is carefully separated from her while she is hatching. In some temperate and warm countries

the hen also lays eggs in the autumn, which are generally used in cookery, as a brood is seldom perfected from them; whereas, those deposited in spring not being more numerous than the mother can hatch, are usually allowed to remain under her care. The young require to be watched with attention, as they are liable to perish from hunger or redundant moisture. In this island they are bred in great numbers, in Norfolk, and some other counties, whence they are driven to the London markets in flocks of several hundreds, the attendants managing them with great facility by means of a bit of red rag tied to the end of a long stick, which, from the antipathy which they bear to that colour, effectually answers the purpose of a scourge. The quality and size of those reared in Norfolk are reckoned superior to those from any other part of the kingdom.

It is sometimes said that though the turkeys reared in Scotland are of smaller size than those of England, they are proportionally fuller of flesh, and in better condition. What degree of abstract truth there may be in this we cannot say; but it agrees with the analogy of the birds in their native condition in America; for those of the southmost and warmest part of the range, are less full of flesh and much tougher than they are further to the north. A turkey certainly rates higher in comparison with a goose in Scotland than in the south of England; but there are two ways in which this may be accounted for—the superiority of the turkey or the inferiority of the goose; and both of these are so equally applicable, that it is impossible to decide between them.

The genera which we have noticed in the geographical section immediately preceding, are wholly American birds, just as those which we noticed in the first geographical section were wholly birds of the eastern continents; and it is not a little remarkable that the American section of the gallinidæ should be chiefly confined to that part of the continent which has the least chance of having had any natural interchange of productions with any other part of the world, but of which the inhabitants are all tempered to the peculiarities of the country itself. If natural history were to be followed out to its geographical arrangement, America southward would make a very distinct province, and present very peculiar and well defined features; and, even in the present state of our knowledge, and totally as, till within these few years, the geography of animals has been neglected, the peculiarities of this part of the world force themselves on the attention of even the least observant.

We are now to proceed to what may, upon the whole, be considered as the gallinidæ of the great northern geographical province of the world; and as in the high latitudes, the east of Asia, and the west of America, are not farther from each other than Norfolk is from the coast of Holland, we may naturally expect an interchange and consequent similarity in their native animals. There are differences no doubt, which are sufficiently striking for being specific in most cases, and even generic in many; but still the whole may be said to belong to the same natural families; nor are we aware that there is in Polar America any bird, or even any species of mammalia, to which there is not something in the northern parts of the eastern continent so nearly corresponding that they may be considered as the same in all their more prominent and more important characters, and similar in all their leading habits.

This is especially the case with that family of the gallinidæ which remains to be considered, which Cuvier retains as the Linnean genus *Tetrao* (grouse), but which he divides into sections or sub-genera, and others divide into separate genera under distinct names. The best way perhaps, therefore, in order to make popular description meet the views of both parties, would be to consider these birds as a family, consisting of grouse, properly so called, and of birds resembling grouse; and thus the proper name for the whole would be

**TETRAONIDÆ.** The only general character which Cuvier mentions as applicable to the whole of these birds, is that of having a band of naked skin over the eye, and this band generally of a red colour, the tint being rich in proportion as the birds are in high condition. This family, in one or other of the numerous genera and species which compose it, is very generally distributed over the globe; and with the exception of South America, where their place is occupied by the timanous, already described, they are found in every land of any considerable extent, and some of them in pretty remote islands of the sea. In some instances they are domesticated; but, generally speaking, they are in a state of free nature. They are very abundant and prolific in all places which are adapted for them; their flesh is both delicate and richly flavoured, and therefore they are highly prized for the table. On this account they are much hunted as game in all parts of the world; and in the British islands they are the only wild and native birds which are recognised as game.

They admit of subdivision into three very distinct genera, or perhaps subordinate groups, and some of these groups admit of farther subdivision, before we come to species. These groups are, *Grouse*, properly so called, *Partridges* and *Quails*. If we take them according to their general distribution in latitude, we may perhaps say that the quails inhabit the most southerly; the partridges next; and the grouse, in one or other of their species, the most northerly—indeed, among the most northerly of land birds which remain in the same localities throughout the year. They are, however, often found incorporated together in the same latitude, though not exactly in the same locality. The quails, true to their geographical distribution, inhabit lowest down, where the climate is warmest; the partridges in the champaign countries, which are a little more elevated, though it is not easy to draw a definite line between them and the quails; and the grouse inhabit the greater elevations; and as they are among the last resident birds near the pole in latitude, they are also in more temperate countries, where they are found in such, the last birds near the sky. We shall not, however, notice them in their usual arrangement, which is usually taken from grouse as the typical genus to the quail; or in the geographical one from the quail to the grouse, which we have now mentioned; but shall begin with the partridge, as the best known in common localities, and the one which is most generally distributed.

**PARTRIDGES** (*Perdix*). The characters of this genus are, the bill short, stout, compressed, and naked at the base; the upper mandible arched, convex, and much curved toward the tip; the nostrils at the base of the bill lateral, and half covered by an arched membrane; the three front toes united by membranes as far as the first articulation; the tail, consisting of

fourteen or eighteen feathers, is short, rounded at the extremity, and drooping downwards; and the wings are also short, rounded, and hollow. Partridges are stationary in some countries, and shift their abodes with the seasons in others. They are very numerous in warm and temperate regions of the globe, living in pairs, and steady in their family attachments. The greatest number reside in the fields and in open tracts of country, with the exception of some, which prefer the outskirts of woods in the neighbourhood of water. Their food consists of grain, seeds, bulbous plants, insects, and worms. They run more frequently than fly, get up from the ground with some difficulty, and make a whirring noise when on the wing. They have numerous broods generally; and the young, as soon as they are hatched, run about—indeed, they may be often seen running with a portion of the shell adhering to their bodies. The species and varieties of partridges are very numerous, so that we can afford to notice only a few of the *leading ones*.

The partridges of the eastern continent admit of subdivision into two sections:—the *true partridges*, which have the bill and tail short, and no produced spurs on the tarsi; and the *francolins*, which have the bill and tail produced, and spurs on the tarsi. The former are strictly monogamous, and fight few battles of mere gallantry, though they fight stoutly for their pastures; but the second are very pugnacious in some of the species. As a whole race they inhabit warmer latitudes than the true partridges. We shall notice them in order; and first the *true partridges*. Besides these there is a third division, the *Colins*, or partridge of North America, which are perchers, having the bill short and stout, and some of them are migratory.

The *Common or Grey Partridge* (*P. cinerea*). The male of this species, when full grown and in good condition, weighs about fifteen or sixteen ounces, and the female about two ounces less; the length of the entire bird thirteen inches, breadth twenty; the eyes are hazel; the bill in the young is brown, in the old bluish white; the legs also are yellowish when young, and, as they increase in age, turn to a dark bluish white. The age of partridges is discovered by the bill and legs; and another method is, from the appearance of the last feather of the wing, which is pointed after the first moult, but in the following year is quite round. The general colour of the plumage is brown ash, elegantly mixed with black, and each feather is stroaked down the middle with buff-colour; the chin, cheeks, and forehead are tawny, and palest in the females. Under each eye there is a spot, with small warty excrescences, and above and behind the eye, towards the ear, is a naked skin of a bright scarlet, which is not very conspicuous, except in old birds; the legs of the male are furnished with a blunt spur or knob behind, and the breast with a crescent of a deep chestnut colour, which takes place the beginning of October; this mark the female wants, and her feathers are in general not so distinct and bright. It is said the partridge, if unmolested, lives from fifteen to seventeen years; others dispute this computation, and maintain that they live seven years, and give over laying in the sixth, and are at their full vigour when two years old. Partridges pair about the third week in February, and sometimes after being paired, if the weather be extremely severe, they all gather together, and again form the

covey. They begin to lay about six weeks after being paired. According to Ray there are one-third more male than female partridges hatched; and it is well known the old cocks will drive the young cocks off the ground, and afterwards frequently fight until they kill each other. In this respect partridges differ from pheasants; they will have a certain range to themselves, whilst pheasants will hatch and live quietly with their broods close together. When too many birds are left, these contentions are sure to happen; and the consequence is a scanty produce, for the female is so pursued, that she drops her eggs in various places, forming no nest, and perhaps never laying two eggs in the same spot. So well aware was the duke of Kingston of this circumstance, that he always had the partridges netted upon his manors as soon as they were paired, and destroyed all the surplus cocks. Mr. White, the naturalist of Selborne, relates that a friend, who was fond of setting, used frequently to take small coveys of partridges, entirely consisting of cock-birds; these he pleasantly, and not inapty, used to term *Old Bachelors*. The late Mr. Doughty of Seiston, who was an excellent and most observant sportsman, once preserved an overstock of old partridges, and declared that he did not believe, for two seasons following, there was a covey of young birds upon a tract of near three thousand acres of as fine breeding land as any in the kingdom; he shot, and encouraged the destruction of this stock of ancients by all possible means; and the result was, that the partridges bred again as abundantly as formerly. The amorous nature of partridges has given rise to very strange accounts; we are unprepared to controvert, and less inclined to investigate, this peculiar propensity ascribed to them. The female lays her eggs on the ground, scraping together a few bents and decayed leaves, which are strewn roughly in the hollow made by an ox or horse's foot. This nest is formed upon hedge-banks, in corn or grass, but more particularly in clover fields; and the number of eggs laid are from fifteen to twenty-five, of a greenish-grey colour: the number of eggs is much reduced when the bird is either very young or very old, and also when the first eggs have been destroyed and a second hatch produced. There have, however, been instances of amazing fecundity in the partridge. On a farm occupied by Mr. Pratt, near Ferling, in Essex, in the year 1793, a partridge nest was found in a fallow field with thirty-three eggs; twenty-three of the eggs were hatched, and the birds went off; four more had live birds in them; the number of the eggs was ascertained before hatching, to decide a bet laid by a person who refused to credit so unusual a production; the female covered all the eggs; seven of which in the centre were piled in a curious manner. A nest was found in 1798 at Elborough, Somersetshire, in a wheat field, with twenty-eight eggs. In June, 1801, at Welton-place, Nottinghamshire, the seat of Mr. Clarke, a partridge's nest was found in a plantation, containing thirty-three eggs.

Upon Sion-hall farm, in Essex, belonging to Colonel Hawker, in 1788, the following extraordinary incident of a partridge depositing her eggs, was known to many persons. This bird chose the top of an oak pollard to make her nest; and this tree, too, had one end of the bars of a stile, where there was a foot-path, fastened into it; and by the passengers going over the stile, before she sat close, she was disturbed

and first discovered. The farmer, whose name was Bell, apprised us of the circumstance, which he laughed at, as being the report of his workmen, and saying that it was only a wood-pigeon they had mistaken for a partridge. But Master Bell, who had killed some hundreds of partridges, so positively affirmed his having beheld the bird upon the nest on the tree, and also, at another time, having told the eggs to the number of sixteen, that he was persuaded to ride to the spot, where the partridge was seen sitting. In a few days she hatched the sixteen eggs, and her brood scrambling down the short and rough boughs which grew out all around from the trunk of the tree, reached the ground in safety. The female sits three weeks, and during that period undergoes a considerable moult, for the feathers of the belly drop : the great hatch is about the first ten days in June ; the earliest birds begin to fly towards the latter end of that month.

Partridges are not every year equally plentiful : in general, when the season is dry during May and June, the birds are numerous ; on the contrary, heavy and frequent rains during the time of laying and incubation, may chill or drown the eggs. If the weather is wet when the young first leave the shell, the cold benumbs the little strength they then possess in their legs, and they die whilst the mother is leading them in search of food to sustain life. At this time too much drought is likewise unfavourable ; the ground cracks from the heat, and into these crevices they fall and inevitably perish ; and this latter spreads a more universal destruction than the former, especially in clayey lands. The old partridge has other dangers to encounter from weasels, stoats, &c., crows, magpies, curs, and shepherds' dogs ; all of which suck the eggs, not to mention the shepherds and farmers themselves, who, in some counties, very kindly destroy them. It is not, under all these disadvantages, an unfair calculation to suppose that one half of the broods in any one year are never reared. When the eggs are destroyed in any of the above ways, the partridges frequently lay again, and the produce of these second hatchings constitute those small birds that are not perfectly feathered in the tail until the beginning of October, and always continue a puny, sickly race, that seldom outlive the rigours of the winter. The affection for its young, which the partridge shows, is peculiarly strong and lively ; by her mate she is greatly aided in the care of rearing them ; together they lead them out, call, and point out to them their proper food, and assist them in finding it, by scratching the ground with their feet : they frequently sit close to each other, covering the young with their wings like the hen ; in this situation they are not easily sprung, nor will the sportsman who is attentive to the preservation of his game, disturb a scene so interesting ; but should the pointer come too near, or unfortunately run in upon them, there are few who are ignorant of the confusion which ensues. The male first gives the signal of alarm, by a peculiar distressful cry, throwing himself at the same moment more immediately in the way of danger, in order to mislead the enemy ; he flies, or rather runs along the ground, hanging his wings, and exhibiting every symptom of debility, whereby the dog is decoyed, by a too eager expectation of an easy prey, to run further from the covey. The female flies off in a contrary direction, and to a greater distance, but soon after secretly returning

she finds her scattered brood closely squatted among the grass ; and, hastily collecting, she leads them from the danger, before the dog has had time to return from his pursuit. Mr. Markwick says he has seen, when a kite has been hovering over a covey of young partridges, the old birds fly up at the kite, screaming, and fighting with all their might to preserve their brood. It is no uncommon thing to introduce partridges' eggs under the common hen ; when she has set the regular time, if the young do not appear, the feathers are glued to the inner surface of the shell, from being exposed to too great heat from the hen. To remedy this, dip the eggs five or six minutes in water, and the moisture will soak through the shell and loosen the feathers ; and this kind of bathing may also, perhaps, refresh the young bird, and give it additional strength to break its prison. It is said that the partridge, bred under a hen, retains through life the habit of calling when it hears the clucking of hens. The first food for the young partridges should be the eggs of the small ant ; afterwards fresh curds, mixed with lettuce, chickweed, or groundsel. It will be some time before they can eat grain readily.

Even when fostered by hand, the partridge seldom forgets its wild origin, and, at its full growth, soon acquires a habit of estranging itself from the house, however intimately it may have been connected with the place and its inhabitants, in the early stages of its existence. This species of partridge is very generally distributed over the eastern continent, most abundantly in the temperate regions, though it also occurs in high latitudes, and, seasonally at least, in hot countries, such as Egypt, and the coast of Barbary. In a bird which is so generally distributed, considerable varieties of colour may be expected, and two of these varieties have sometimes been described as separate species : these are the Damascus partridge, which is only about half the size of the common variety, pale ash colour above variegated with black and red, and yellowish white on the under side ; and the hill partridge, which is smaller than the common variety, and darker in the colour. These and some others can be regarded as little else than climatal varieties, and there are instances also of albinos, or specimens nearly or altogether white.

*The Red-legged or Guernsey partridge (P. rufus)*, is larger than the common one ; and the following are its characters : the bill and irides are red, the forehead is grey-brown, the hind head is red-brown, the chin and throat white encircled with black, to which is added a band of white over each eye to the hind head ; the forepart of the neck and sides of it are cinereous, with two spots of black on each feather, the hind part of the neck red-brown, the back, wings, and rump greyish brown ; the breast pale ash colour ; belly, sides, thighs, and vent red ; the sides marked with similar streaks of white, black and orange ; quills grey brown, with the outer edges yellowish ; the tail composed of sixteen feathers, the four middle ones grey brown, the next on each side the same, but rufous on both sides ; the legs are red, and the male only has the blunt knob or spurs behind them. This species is abundant in the south of France, and generally in the warmer parts of the south of Europe ; and it is probable that it may be a climatal variety of the Greek partridge, which is very abundant in Greece, in the islands of the Archipelago, and in the west of Asia. It is not understood as being a native of any part of the main land of Britain ;

but it is common in the isles of the channel, and it is on this account that it has got the name of the Guernsey partridge. It has been introduced into various parts of the south of England, with different success in different instances, though in many parts it is now fully established. It is generally reported that when the red-legged partridge establishes itself, the grey partridge disappears, and it probably is driven off by the stranger, which is the larger and more powerful bird. It is doubtful, however, whether the exchange be a wise one. The red-legged partridge is certainly larger than the common partridge, and it is also a more handsome bird; but it is questionable if its flesh is as good for the table; it is whiter in the colour than the flesh of the grey partridge, but it is inferior in flavour and not so juicy. It seems indeed to be a law in wild birds, that those which have the flesh exceedingly white have it with less flavour: it is also a much less social species than the last; and the same degree of union does not exist among its flocks. The male does not partake in the incubation, and leaves the care of the family entirely to the female: she forms her nest in the fields and bushes, and lays from fourteen to eighteen eggs, of a dirty yellow, marbled with large red spots, and powdered over with small ash-coloured points.

**THE GREEK PARTRIDGE** (*P. saxatilis*). The upper parts of this species are bluish grey, the front and naked skin round the eyes black, the cheeks, throat, and upper part of the neck pure white, divided by a band of black; the scapulars and principal coverts ash colour with yellowish tips; the top of the head and sides of the neck ash grey; the flanks furnished with grey feathers, crossed by alternate bands of black and white, and reddish brown at the terminations; all the under parts yellowish, fourteen ash-coloured feathers in the tail, the five lateral ones on each side with red tips; and the bill, a small circle round the eye; and the feet red. The length of the male bird is about fifteen inches. The colours in the female are less bright. This species, if species it be, and not merely a variety, differs from the Guernsey partridge in nothing but in being rather larger, and more inclining to ash-colour: it is found in the south of Europe, and also in the west of Asia, in which last country and in Greece it is very abundant; and in some places the people engage the males in pitched battles. There are several other partridges mentioned as occurring in the south of Europe, but they have no great claims to popular distinction. The rock partridge, for instance, is very like the Guernsey; and, indeed as the character of the ground changes, there are considerable changes in the partridges. This holds in Asia as well as in Europe, where the red partridge, or Greek partridge especially, appears to be broken down into a number of varieties. We shall merely mention one or two of the names:—

**Hey's Partridge** occurs in Arabia, and also in Nubia and Upper Egypt. Upper part clear grey ash clouded with cream-colour; head reddish ash; wing-coverts cream-colour, finely streaked with brown; quills brown marked with white on their outer webs; tail-feathers rather long and reddish; under part reddish brown, beak yellow, feet ash-coloured; length only eight inches.

**Yellow-bellied Partridge.** Inhabits west of Africa, south of the Desert. Upper part deep grey, marked with black and red; under part the same colour, unbroken except by a yellow band across the belly;

bill ash-coloured; feet yellow; length about nine inches.

**Eyed Partridge.** An Indian species. Fore part bright red; back banded with black and white; rump marked with triangular spots of chestnut; wing-coverts olive with black spots.

From the specimen which we have given of those foreign partridges, and if mere differences of size and colour were to be made grounds of specific distinction, the list might easily be extended to several dozens. There is, however, no interest for the general reader in such distinctions, because the main character of the birds and their manners vary little, notwithstanding those modifications of external appearance; and when the character and habits of one species or one variety, such for instance as the common grey partridge, has been well explained, it will answer for all the rest excepting in the very trifling circumstances of locality and colour.

**THE FRANCOLINS** need not detain us long. We have already mentioned that their enlarged bills, longer tails, and spurs on the tarsi distinguish them from the true partridges; and that it is generally these birds, and not the real partridges, which are engaged in pitched battles for gambling purposes. One species at least inhabits the south of Europe, and indeed the name francolin is nothing else than the Italian *Francolino*, which means "free," and as applied to birds, it really means such as are not free, at least to all the people, but such as are prized as game, and protected accordingly.

It is not, however, in the differences of structure to which we have alluded that the chief distinctions between the partridges and the francolins consist. The partridges are birds of the open champaigns, reposing at night on the ground. The francolins prefer the shade of woods, and perch for the night in trees. They also feed more upon animal matters, such as mollusca and worms, and they resort more to marshy places, and find part at least of their food by searching the mud of these with their bills. The difference in their structure accords with their habits. The enlarged tail enables them to rise with more facility than the partridges; and the more powerful bill enables them to poke in the mud and mire. Their voices are also much louder and harsher than those of the partridges; and they utter loud calls in the morning when they leave their perches, and in the evening when they return to them. But though they perch on trees for the night, the females nestle upon the ground, and rear their young very much after the manner of partridges, at least until they are so far fledged as to be able to fly to a perch.

**Collared Francolin** (*P. Francolinus*). This is the species which is found in the south of Europe. The upper part is black, rayed with white; the top of the head and the nape black, with yellow edges to the feathers; there is a white band under the eyes; the forehead, the space over the eyes, the throat, and all the under parts are deep black; but there is a broad distinct collar of maroon brown round the neck. The coverts of the wings are brown, with rays and spots of red, and the quills are black. The under tail-coverts are red; and there are large white spots on the flanks. The bill is black, the legs are reddish, and the spurs brown. The length of the full grown male bird is about twelve or thirteen inches. The female is rather smaller, of a yellowish fawn in the ground colour, streaked with red, grey, and brown on

on the upper part, and with brown on the neck and all the under part of the body.

*Pondicherry Francolin.* This species is also called the Pondicherry partridge; and indeed all the francolins and also the colins are partridges in common speech. As its name imports, this species is found in India, but it is of course not confined to the neighbourhood of Pondicherry. It came first from that place to France, and is one instance of the absurdity of calling animals after confined localities.

The upper parts are red, with zigzag bands of white; the top of the head reddish ash; the back of the neck grey, and streaked with black; the primary quills are pale ash, the secondaries red, with white round eyes; the rump is grey, mottled with black and white; the tail-feathers are brilliant red, bordered with black, except the two middle ones, which are russet, finely pencilled with brown, and crossed by four bands of yellow; the chin and upper part of the throat are yellow, with minute black spots; the breast pale rose-colour, waved with black; the belly white, with crescent-shaped black spots; the flanks are reddish with white spots; the bill is blackish, and the feet red. The length of the male is about ten inches. The female is pale fawn-colour, streaked with black on the upper part; the quills have black tips, and the coverts of the wings have nine or ten bands of white, with black at the ends; the head, the neck, and the upper part of the breast are brownish white, spotted with black; the lower part of the breast is white, and the belly brown with black lines.

*Pearled Francolin.* This is another eastern species, being found both in India and China. Upper part deep golden red; top of the head black with red margins to the feathers; front yellow; and sides of the head white, with a black spot on each: the quills black rayed with white; the coverts bright red, barred with black; the back of the neck and the breast black, and spotted with white, from which the name "pearled" is derived; the abdomen black, with small points of reddish; the bill black, and the feet red. Length eleven inches: the female is smaller. She has a black streak behind the eye; the feathers of the upper part margined with bright brown, and irregularly spotted with white.

There are many other species or varieties described in the catalogues, but those to which we have alluded must suffice as a specimen: nor should we, even if we were to detail the whole with the greatest minuteness, be thereby adding materially, or almost in any degree, to the quantity of useful knowledge; we should be merely mentioning a few more varieties of colour, and slight differences of size; for the habits of the birds are so nearly alike, that when we have mentioned in what they differ from the true partridges, we have told almost the whole tale of their natural history.

THE COLINS, or partridges of North America, differ in many of their habits, both from the partridges and the francolins of the eastern continent, or rather they combine many of the habits of both. They inhabit indiscriminately the open places and the woods, and sometimes parks, and at other times seek a sequestered repose upon the ground. The nest is, accordingly, sometimes in a bush, and sometimes in a tuft in the open prairie; but it is always formed of the same materials, and put together in the same rude manner. It is composed of a few sticks, lined with withered stalks and grass. They are very prolific, the eggs in a

single hatch being rarely fewer than fifteen, and often as many as five and twenty. When one brood have broken the shell, the male, at least in some of the species, takes the rearing of them, while the female proceeds with another hatch. All the hatches of the season are united into one flock, but as the birds are sought after with much avidity, both by the settlers and by the aboriginal inhabitants of the forests, and as they have besides many enemies, their numbers are very much thinned every season, before the time of reproduction again comes round.

These birds, many of which are recent additions to natural history, and of most of which the history is very imperfect, have been indiscriminately called partridges and quails. They have many points of resemblance to both; but in strict propriety they belong to neither; and thus they have been formed into a separate genus, under the name *Ortyx*. Some species have been mentioned as inhabiting South America, at least as far to the southward as Guiana, and the valley of the river Amazon; but there seems to be some little doubt on the subject. It may, however, be true that they pass gradually from the more typical ones of the north to the timanous of the south; but we are not yet in possession of any connected chain of data that will bear out such a conclusion. This consideration, as well as that of space, which the interest of this order of birds has already tempted us to exceed, force us to confine ourselves to the mere naming of one or two of the species.

THE VIRGINIAN QUAIL, OR PARTRIDGE (*Ortyx Virginianus*), inhabits the temperate parts of North America, and generally perches on trees. According to the accounts, this species appears to have at least one of the habits of the partridge, that is, it follows, rather than it crosses, the progress of cultivation and improvement. In this respect it is very different from most of the animals of the wild forests of America. These have, in general, fled before the march of the axe and the plough; and no more vestige of them remains in the places which are settled than if they had never been there. But the quail (as it is termed) is said to have come to settled places in which it was quite unknown while they remained in a state of nature. This is the case with the partridge, but with the partridge only among our analogous birds. The common quail has disappeared from England, and occurs only as a visitant, or if as a resident, is very rare. The grouse is also now unknown in many places where it was once abundant; but the partridge is more abundant than ever; and as the heath plants give way before the sheep farming, and the harsh tuft sward yields to the plough, the heath birds depart, and the partridge occupies their place. Such is reported to be the case even with Canada; and the birds have come in from the west, and not yet made their appearance in the valley of the St. Lawrence, below the fall of Niagara; but they have been described as resting in the fields of Upper Canada after dark, and uttering cries similar to those of partridges when they jug.

The Virginian quail, which must be widely extended, as it has also been called the northern quail, the Maryland quail, and the Mexican quail, has the upper part yellowish red, with ash-coloured and black borders to the feathers, and large black spots with red borders down the back. The scapulars and coverts are variously marked with ash-colour, brown and black. The smaller coverts are russet with

black lines. The quills black; the tail-coverts bluish ash; the front black; a double white line over the eye; the throat white with some black streaks; spots of white, russet and black on the head and neck; the breast reddish white, with cross streaks of black; the belly white with several spots of black; and the flanks red with small oval white spots, surrounded with rings of black. The bill black at the tip and reddish at the base, and the feet brown. It is a small species, the length being only between eight and nine inches. This species has been brought alive to Britain, has bred readily, and is domesticated in some parts of England, in Suffolk we believe, or at all events it is understood as being permanently established there.

*Californian Quail (Ortyx Californica).* This species, as the trivial name imports, is from the west coast of North America; but it is also found in Mexico, and appears to have been described under different names. The colours are various shades of brown, slate blue, and ash grey, picked out with red, black and white, and finely mixed and contrasted. The male has a black crest on the top of the head, part of the feathers of which curl forward. The female is without the crest, and has all the colours less bright.

Many other species or varieties have been named, and it is probable that many more may yet be discovered in a country so wide and wild, and so well adapted to the habits of such birds, as North America. But so little is known respecting them, and they appear to differ so little in manners, that they cannot be made interesting in a popular point of view.

*QUAILS (Coturnix).* The quails are smaller in size than the partridges, have the bill slender, no red membrane over the eye, and no spurs on the tarsi. In other respects, they bear a considerable resemblance to the partridges. The true quails are all natives of the eastern continents, and they are not found in the very cold latitudes. Although a more minute race than the partridges, the quails are more active birds, more discursive and prone to migration. They seem to admit of two divisions, the quails, properly so called, which have hind toes more or less produced; and those which have no hind toe, and which, for that reason, Temminck called *Hemipodius*, or half-footed. There is one structural character in the quails which is worthy of being borne in mind, as it explains, in part, why they are much more discursive in their habits than the partridges, and others of the family, or indeed than most of the gallinidæ. They have the first quill of the wings as long as the others, and thus their wings being less rounded are better adapted for long flight.

*Common Quail (Coturnix major)* has the upper part mottled with brown and grey, with a whitish or reddish streak along the middle of each feather. The top of the head is mottled with black and red, and marked with three longitudinal stripes of brownish white, the two lateral ones passing nearly over the eyes. The throat is black; the breast russet; the belly and thighs whitish; the bill black, and the feet flesh-colour. The length of the full grown male is between seven and a half and eight inches. The female has the breast white, spotted with black. Quails are subject to considerable varieties of colour, some being found much darker than the average, and others nearly all over yellowish white. The young of the year resemble the female, after which they vary

considerably in colour. Food and confinement have a good deal of effect upon their colours; for when they are kept under restraint and fed upon hempseed all their colours merge in one uniform brown. They are much longer winged in proportion to their size than most of the gallinidæ, the extent of the wings being about double the length of the body, while in the others it rarely exceeds one and a half. The common quail is found pretty generally throughout continental Europe, ranging nearly as far to the north as Lapland. It is also found in Asia, and is abundant in the south of Siberia, but is not met with in that country so far north as the shores of the Arctic Sea, or even in such high latitudes as it occurs in some parts of Europe. In China, and the countries farther to the southward, the common quail is very abundant, and there are also other species. They extend unto the eastern islands, and are very abundant in some parts of Africa. Though quails are more accustomed to running than flying, and although, for the most part, they are incapable of remaining for any length of time on the wing, without experiencing lassitude and fatigue, it is nevertheless certain that they undertake pretty extensive migrations, and in immense flocks, passing from the colder to the warmer latitudes in autumn, and retracing their way in spring; and there is reason to believe that their passage, notwithstanding the opinion of Colonel Montague, usually takes place in the course of the night, for they are accustomed to sleep, or at least to repose, during the greater part of the day, hiding themselves in the tallest grass, where they are sometimes run in upon by dogs before they are flushed. They are met with in many parts of this island, but seldom in any considerable numbers. They leave us in August or September, are supposed to winter in Africa, and return early in the spring. On their arrival at Alexandria, such multitudes of them are exposed for sale, that the crews of merchants vessels are fed on them, and complaints have been laid at the consul's office by mariners against their captains, for giving them nothing but quails to eat. They have been known, when having wind and weather in their favour, to perform a flight of fifty leagues across the Black Sea in the course of a night. On the western coast of the kingdom of Naples, in the vicinity of Nettuno, sometimes quails have appeared in such prodigious quantities, that a hundred thousand have been caught in one day, and within the limited space of three or four miles. The principal part of them were conveyed to Rome, where they are in great request, and fetch a very high price. Along the shores of Bovenia, especially on the lands belonging to the bishop of Frejus that border on the sea, they alight in such vast numbers in the spring, that for the first two or three days they are occasionally found so exhausted as to be caught with the hand. In some parts of the south of Russia they so much abound, that during the periods of their migration they are taken by thousands, and are sent in casks to Petersburg and Moscow. The English import not a few from France for the table, all of them males. They fight fiercely for the females, whom they abandon when incubation commences. The hen bird scrapes a hole in the ground, generally in a corn field, and consigns to it from eight to twenty eggs, of a bright green colour, dotted with minute blotches of brown or black. The incubation lasts three weeks; and the young, which are produced covered with down,

run on coming out of the shell, and are much sooner able to provide for themselves than the young partridges are. To such of them as happen to be produced on a strong argillaceous soil, drought is very unfavourable and they are very apt to die in consequence of getting entangled in the fissures. The mother continues by them till the autumnal migration, at which period solitary quails are seldom met with; but, though living in small flocks of four or five, when started they disperse in different directions, and quickly reassemble near the spot from which they were roused. The young utter a feeble and plaintive cry when they wish to flock together. That of the adults is more harsh and grating, and the males are readily decoyed by the quail-pipe, with which the fowler imitates the call of the female. From the pugnacious dispositions of the males, they were exhibited by the Athenians and Romans, in regular combats; and in China, Sumatra, and some districts of Italy, the practice of quail fighting is still cherished. As quails are reckoned very delicate eating, and are capable of receiving a considerable quantity of fat, they are killed in great numbers for the table; but they will not breed in a domesticated state.

*Chinese Quail.* This species is of course abundant in the country after which it is named; but it is not confined to that country, but ranges pretty extensively over the Philippines, and the other islands to the eastward of China. It is a very small species, not above four inches and a half in length; but it is a pretty little bird, easily tamed, and the Chinese are reported to make use of it for the purpose of warming their hands, and likewise rear it for fighting. The colours are: upper parts of the body brown, sprinkled with black spots, and white lines, throat black, arches on the neck white, the middle of the belly chestnut.

*New Holland Quail.* About seven inches in length. Upper part clouded chestnut streaked with black, and with white shafts to the feathers, under part reddish ash, with black crescent spots placed cross-wise.

There are numerous other species or varieties described by authors or preserved in museums; but it does not appear that they have any marked characters in which they differ much from the common species.

*HEMIPODIUS.* As already mentioned, these birds differ structurally from the quails in being entirely without hind toes. They are in general inhabitants of dry and sandy places, in running upon which the hind toe would be an incumbrance to them rather than any thing else; and hence we find that in all birds which inhabit sandy places the hind toe is either wanting, or merely rudimental. These birds are little known, because they have no European type, and also because they frequent those parts of foreign countries which Europeans visit the least. They appear to be altogether confined to the southern and eastern world, and to have a locality in that direction more remote from Europe than any other of the gallinidæ. Among them may be mentioned the fighting quail of Java, which the inhabitants of that country engage in gambling battles, as was done with game cocks in barbarous times and places of the western world. We must not, however, wonder at the Javanese for being so deeply interested in the issue of a battle between those comparatively small

birds; because, among the natives of that country nothing is more common than for a man to stake first all his property, and then the freedom of his wife and children, upon the issue of a duel between two black beetles, whose battle takes place in a little chip box.

The *Heteroclyte* (*Syrhaptes*) may be considered as forming the last of this division of the order; and, indeed, it is not very easy to find out its proper place in the system, as it is not, strictly speaking, either a quail or a grouse, though, according to the description, it partakes of the characters of both. There is but one species, which inhabits the extensive sandy plains of central Asia, to the southward of the lake of Baikal; and for the knowledge of it naturalists are indebted to Professor Pallas. And as for its habits we know very little of them, excepting that it lives in very bare and desolate pastures, and must, from its structure, depend much more on its wings than on its feet in searching for its food; and this peculiarity takes it not only out of the properly established groups of partridges, grouse, and quails, but out of the order of *Gallinidæ* altogether, with which, however, they may use the wing in perching, in migrating, or for other purposes; without almost one exception they make use of the foot in searching for their food. The feet of this bird are peculiar: the tarsi are very short, and so are the toes, and they are completely feathered, so as to have the appearance more of a defence against extreme heat or extreme cold than any thing else. The wings are much longer than in most of the order; and they are differently formed, being adapted for long flight and ready turning when in the air, as the first quill is the longest. The two middle feathers of the tail are also considerably produced.

The generic characters are: the bill short, slender, and conical; the upper mandible slightly arched, with a channel on each side of the culmen, and the nostrils basal and lateral, and covered with the feathers of the front. The feet with only three toes, all to the front, united by membrane almost as far as the claws; the tail-feathers increase in length in regular stages from the sides, except the two middle ones, which are elongated and very narrow.

*Pallas' heteroclyte* (*Heteroclitus turtaceus* of Vieillot) is the only known species. It is yellowish ash on the upper part, with black margins to the feathers, and a number of crescent spots of black along the back. The top of the head is marked by a line of similar spots; the sides of the neck are orange yellow, of which the tint is brighter on the throat. The coverts of the wings have purple red on the tips; and the quills are black, with orange yellow on the margins of the webs. The tail-feathers are yellowish ash, with white tips, except the two produced ones, which are black. The belly is yellowish ash, and the rest of the under part whitish, the former bordered with a large band of black. The bill is yellowish, and the claws black. The length of the male bird is about a foot. The female differs little in size or in markings, but is very easily distinguished from the other sex by wanting the produced tail-feathers which form so peculiar a character in the male.

The Tartars call this bird *Tsadscha*; and describe it as being rare, or, at all events, rarely seen. They are wild, and the people can kill them only with their arrows; and as they inhabit the wild and bare places, where there is no pasturage, and little other

inducement of any kind for the people to resort to them, the birds are but very little known, even in their native locality. Their food is, accordingly, but little known; but it is supposed to consist, in part at least, of small insects, which are among the chief productions of the wilds. Those who have observed them with the greatest care, represent them as walking very slowly, and with apparent difficulty, so that they are obliged now and then to squat down for the purpose of resting themselves. On the wing they are a good deal more active, flying rapidly, and at a considerable elevation; but they do not continue long on the wing at a time. Their habitation is among the bare and shifting sand of the deserts; and, in addition to insect food, they scrape the sand for those small seeds which are drifted into it by the winds; and which, from the perfectly sterile nature of the soil into which they are brought, would be lost, were it not for these birds. Delanane mentions that, in his passage across these wilds, toward the Chinese frontier, he often came upon the females in the act of incubation; and that he found them such close and pertinacious sitters, which would not quit their eggs till the very last extremity. The nest he mentions as very rude, consisting of a small hollow in the sand, lined with a few such withered leaves of hard grass as can be picked up in the places which the birds inhabit. The eggs are represented as being uniformly four in number, which is different from that of any species of *gallinidæ*, which is well made, and forms another reason for doubting whether these birds have been referred to their proper place in the system.

Such is nearly the sum of all the information that we possess respecting one of the most singular of birds, both in its structure, and in the regions which it inhabits. How it may summer and winter in those dismal wastes, it is not easy even to conjecture; but it shows that the sterility of a region must be extreme indeed if it cannot furnish support to some living inhabitant. This bird appears to be at home amid bare stones and loose sand, and in such places only; for, according to the accounts, it never resorts to the more fertile places. Nor is it at all impossible that, even where it inhabits, the end of autumn and the beginning of winter may be the season of plenty, as well as it is in those places where there is a crop and harvest of vegetation upon the ground. The seasonal winds sweep over those regions with great violence, as is testified by the storms which rage upon the lake Baikal, where the winds of the desert and of the inland country may be said to meet; and they must, while the heat of the sand continues, bring with them a number of seeds, and along with these, or rather in them, a number of the eggs of those insects, the appearance of which, in such deserts, could not otherwise be very easily accounted for. But we must proceed with our notice of the remaining group or family of the *Gallinidæ*.

**GROUSE.** Grouse admit of division into two sections; the grouse properly so called, which are inhabitants of woods, heaths, and other places which are wild, but not destitute of vegetation; and wild grouse, which, as the name implies, are found chiefly in the arid wastes. The former have what may be considered as a polar habitat; or, in more temperate climates, they are found only in elevated and comparatively cold places. The latter are found farther

to the south, as there are no arid or sandy places in countries which have polar latitudes. The reason of this is very evident; but still it is worth mentioning, as helping to carry us on towards a proper understanding of the adaptation of animals to their haunts.

The grouse, properly so called, notwithstanding their differences of appearance, form altogether a very natural and well defined family. They are conveniently divided into three sub-genera, or sections: — *Tetrao*, in which the toes are bare of feathers; *Bonascus*, in which the toes and tarsi are feathered on the upper sides; and *Lagopus*, in which they are feathered down to, and also under and between, the toes. All of them have the tarsi feathered, which forms a distinction between grouse and partridges. The first inhabit most southerly and lowest down, bordering on the pastures of the partridges; the last are the most northerly and the most lofty inhabitants; and the second, or those with half the tarsi feathered, are intermediate between the other two. They are all birds of the north of the one continent or the other, or they are common to both; which latter appears to be the case only with the feathery-footed race which inhabit the extreme north. All the grouse are highly interesting birds, as they inhabit the wild places only, and do no harm to man; and they breed very rapidly, and all furnish choice dishes for the table, but our limits will not admit of more than a few brief notices. In doing this we shall take the bird of the eastern continent, and the one of the western, which appears to agree most nearly with it in immediate succession.

**TETRAO or grouse, with the tarsi bare of feathers.**

*Black cock (T. tetrix.)* This species belongs to the eastern continent, where it inhabits the low and sheltered moors, and the borders of streams and marshes. It is a bird of considerable size. The male is about two feet in length, and three feet in the stretch of the wings; and when in prime condition, which is in the early part of winter, the weight is from three to four pounds. The upper parts of the body are black, glossed with rich reflections of purple, blue, and bronze green. The blue is finest on the neck, and the green on the feathers of the tail, purple being the prevailing lustre on the back. The under part is deep and dead black, with the exception of the under tail-coverts, which are white. A spot on the reverse of the wing, the tip of the bastard wing, the bases of the quills, except the first four, and the tips of the secondary quills are also white. The wings are broad; and the tail consists of sixteen feathers, the external ones a little produced, and curling outwards, so as to form a peculiar fork. The naked space over the eye is of a very bright scarlet colour, and granulated. The female is about one-third less in the lineal dimensions than the male; the tail is not so much produced, and the forking is barely perceptible. The general colour is brown, deeper on the back than any other part, and mottled all over with black.

They frequent the sequestered places where there are brushwoods and copses; and perch during the night, though they feed upon the ground. In autumn they eat wild berries and seeds, in winter the buds of trees, and it is probable that during the time when the buds are over, and the seeds and berries not ripe, they feed, in part at least, upon insects and worms.

In autumn and winter the males live in flocks and

at peace ; but when the warm season sets in, and they put on the rich glosses of their nuptial plumage, they fight lustily for the females, as is the case with all polygamous birds. At this period, which is earlier or later in the year, according to the season and the place, but seldom before March or after April, in the British Islands, they are astir by the streak of dawn, crowing, uttering a harsh grating sound, like that of the sharpening of a knife, and otherwise making as much noise in the cold as they can. The eggs are about eight in number, and less than that in the case of a second brood. The nest is rude and on the ground, and the female does not perch until her brood are able to perch along with her. During this time the male remains in the close vicinity of the females, watching them and their broods with great attention ; and, when the broods are matured, he joins the other males for the season of celibacy. If the male is killed early in the season, the females join the neighbouring harems ; but they remain true to the same male for the season if he remains alive. The external distinctions of sex do not appear in the young till the season is far advanced.

The black cock, or black game, are found in many parts of the British Islands ; but more abundantly in some parts of Scotland than in England. They are also not uncommon on the continent, but there also they prefer the more northerly countries, though not the extreme of the latitude.

In Sweden and the other cold countries of the north, where the snows fall heavy and lie long, the black cock betake themselves to snow-houses, as is the case with the other ground birds, and with many of the human race, as, for instance, the Esquimaux, in the extreme north of America. They form burrows, with a breathing aperture, or often with two, in order that they may escape from the predatory mammalia. During their retreat in these places, they eat very little, and do not require it, as the temperature is low and uniform, and they have no action that can occasion any waste. These birds are highly prized as game, though their flesh has not perhaps so much flavour as that of some of the others.

The *Dusky Grouse* (*T. obscurus*) is the American species, which appears to agree in most particulars with the black cock of the eastern continent. In size and colour it is very nearly the same as the European species ; but the tail of the male bird is very differently formed. It consists of twenty broad feathers, the tips of which individually are rounded, as is also the general outline of the tail. The colours of the female also resemble those of the females in Europe, only there are more white mottlings on the chin. The size of the female also bears nearly the same proportion to the male as in the European species.

The form of the tail in this species indicates a more constant habit of ascending and descending than that of the black-cock, a more woodland bird in short ; and this is confirmed by the locality and the habit in so far as observation has gone. The birds are found in the elevated places of the rocky mountains ; and the first known specimen was obtained in 1820, by Major Long, at an elevation of 2000 feet, above the level of the sea, and to the westward of the water-shed between the rivers of that place to the Pacific and the branches of the Mississippi. We are not aware that any specimen has been met with, either in the central valley or in the hills towards the Atlantic. The habits of the

bird are altogether unknown, further than can be inferred from its being a grouse, and inhabiting mountain thickets.

The *Wood Grouse* (*T. urogallus*) is a species peculiar to the eastern continent, and it is one of the most celebrated both for its size and its beauty. It was once an inhabitant of the forests in the north of Scotland ; but it is extinct there now ; though very common to the north of the Baltic, and also in most of the pine forests immediately to the south. In those places where it is abundant, several species are noticed, differing from each other in size, colour, shape of the head, and some other particulars ; but these are of too trivial a nature to be admitted into a hasty general sketch, in which we must confine ourselves to the average or prevailing character.

The neck and upper parts of the body are of a dusky colour, waved across with ash-colour ; the under part is also dusky, but rather paler in the tint, and marked with white spots ; and the under part of the union of the wings with the body is also white ; the breast is green with rich bronze reflections ; and the tail is black with two white spots near the tip of each feather. The length is about two feet nine, and the extent of the wings about three feet. The female is about half a foot shorter than the male, and proportionally less in all her dimensions. She is mottled all over the upper part with dull red, black and white ; the throat and breast brighter red. The young males resemble the female till the first moulting, when they begin to show a little green on the throat.

This is truly a splendid bird, equal in size to the turkey, at least on the average, as reared in confinement. The common weight is about seven or eight pounds, but specimens have been found as heavy as fifteen pounds.

These birds are chiefly confined to what may be considered as the northern zone of the eastern continent, that is, not to the south of the Altaian mountains, on the east of Asia, or of the arid flats northward of the Caspian, in the west, while in Europe they are very rare to the south of the Carpathian ridge, and not abundant even on the northern slopes of these mountains. The great pine forests of the north are their favourite haunts ; and they disappear when those forests cease to exist.

Their principal food appears to consist of the berries of the juniper, the vacciniums, and other small fruit-bearing shrubs of the high latitudes, and also of the buds and young sprouts of pines, the buds and succulent leaves of various plants, and probably also worms and insects. These birds, like domestic poultry, swallow small pebbles, and scratch the soil with their feet. They resort to the copes for food in the morning and evening, and during the day they retire into the thickest recesses of the woods. About the beginning of April their breeding season commences, when they perch with little interruption, and when the male may be seen, at sunrise and in the evening, much agitated on one of the largest branches of the pines, with his tail expanded and raised, and his wings drooping, sometimes walking backwards and forwards, with his neck stretched out, his head inflated, and his eyebrows of a deep crimson. His wooing call commences by a sort of explosion, instantly followed by a sound like the whetting of a scythe, which ceases and recommences alternately for about an hour, and is then terminated

by a similar explosive noise as at the beginning. He is apparently so deaf and insensible, during this singular exhibition, that, though at other times very wild and vigilant, the sportsman may gradually approach him, and take a fatal aim. This ardour of temperament continues till June. The female deposits in an artless situation in her nest on the ground, and among moss, from eight to sixteen eggs, which are about the size of those of the common hen, but more obtuse at the ends, and yellowish white, sprinkled with yellow spots irregularly. When she quits her nest in search of food, she covers the eggs over with leaves or moss. The young, immediately on their exclusion, follow her with great agility, and she leads them to procure wild berries, and the pupæ of ants. The brood follow the mother for nearly two months, at the expiration of which period the young males entirely forsake her, living till the beginning of spring harmoniously together, when they separate and affect solitude, never approaching but in the spirit of hostility, every male being jealous of an intruder, and resisting him with determined obstinacy. In the provinces of Smaland and Gothland, in Sweden, a hybrid but barren offspring is produced between the present species and the black grouse. The flesh of the former, though very dark coloured, is much relished by epicures, when it has not contracted too much of a bitter flavour, by copiously feeding on juniper-berries; and it is often conveyed in winter, in a perfectly eatable state, from Norway to this island. The eggs are accounted preferable to those of every other bird, and are very much in request. But all attempts, it appears, have failed to habituate the species to confinement in a poultry yard.

*The Cock of the Plains (T. urophasianus).* This species is mentioned, by the writers on American ornithology, as approaching most nearly to the wood grouse of the eastern continent. That it does so in size is true; but both its appearance and its habits are different. It is not, strictly speaking, a woodland bird, but rather an inhabitant of the margins of the woods; and we believe the older hunters in North America used to give it the name, "The Prairie Turkey." The tail is very different from that of the European, which is narrow and tapering, and does not indicate so frequent a habit of ascending and descending as the broad-tailed bird of the east. This, like the other American species formerly mentioned, is understood to range to both sides of the Rocky Mountains; and as far at least as California to the south. It is mentioned as being but very indifferent as an article for the table, although it is of such large size. Its food appears to be the leaves and buds of various plants, which are found in the wild places where the bird itself has been met with.

The male, when full grown, measures thirty inches in length; the female is considerably less. The general colour of the plumage of both birds is brownish black; but the female has the fore neck and breast streaked with greyish white; and the feathers of the neck in the male, but not in the female, are produced, something like those of the hackle of the common domestic cock. The pairing time of these birds is in the spring; and the late Mr. Douglas, who is an excellent authority in such matters, says that "small eminences on the banks of streams are the places usually selected for celebrating the weddings; the time generally about sunrise. The wings

of the male are lowered, and buzzing on the ground; the tail spread like a fan, somewhat erect; the bare yellow oesophagus inflated to a prodigious size, fully half as large as his body; and from its soft membranous substance being well contrasted with the scale-like feathers below it on the breast, and the flexile silky feathers on the neck, which, on these occasions, stand erect. In this grotesque form he displays, in the presence of his intended mate, a variety of pleasing attitudes. His love-song is a confused, grating, but not offensively disagreeable tone—something that we can imitate, but have a difficulty in expressing, ending in a deep hollow tone, not unlike the sound produced by blowing into a large reed." These birds build in the plains, on a tuft on the ground, or near water. The nest is carelessly put together, and is constructed of twigs and dry grass. The colour of the eggs is wood-brown, blotched irregularly with chocolate brown at the larger end; they equal in size those of the common hen, and in number they vary from thirteen to seventeen. The time of incubation is about twenty-one days; and shortly after the young are hatched they quit the nest.

These birds appear to belong chiefly, if not exclusively, to the west side of America; and the places of their habitation are those naked plains where there is no vegetation exceeding a bush of very humble growth. It is impossible, therefore, that they can be perching birds, as the wood grouse of Europe is, simply because they have nothing on which to perch. Their wings are feeble and of small dimensions in proportion to the size and weight of their bodies; and their progress through the air is, consequently, effected rather by a fluttering motion, than by a direct and continuous flight. They rise flutteringly at first, giving a few hurried strokes with their wings; and after flying for a short distance, with a wriggling course, and making much whirring sound with their wings, they again alight.

During the summer, and greater part of autumn, these birds continue in families; but when the cold weather begins to set in, the families form into packs, which sometimes amount to several hundreds. Seeds and small fruits are their food at this season, and they get fat; but, as already noticed, the quality of their flesh is very inferior.

*Richardson's Grouse (T. Richardsonii).* This is another American species of the Rocky Mountains, and, like the preceding species, understood to be most abundant to the westward of the summits. It is a much more upland and woodland bird than the last, more graceful on the wing, more active in its motions, and far more valuable as an article of food. The sides of the head and throat black, with pure white spots; feathers on the breast black, with pure white spots; white spots also on the flanks, and the under tail-coverts white; tail, sixteen feathers, rather long, rounded. Female smaller, less black, but more rusty; general colours duller. Nest in bushes, eggs not so numerous as in many of the other species. The male is dull lead-colour and brown, variously blended and contrasted. The female is yellowish brown and black, with some white streaks. The weight is between two pounds and a half and three pounds.

April is the pairing time; and the nests are placed on the copes on the hills, but not high upon the mountains. The eggs are from a dozen to twenty, as

large as those of a hen, and with red spots on both ends. The female sits about three weeks. They eat buds and berries; their voices are soft and murmuring; their flight straight forward, steady, and graceful. They perch in the thick pine trees, and when they are to take wing from a perch, they get an impetus by dropping down, and then dash onwards.

*Sharp-tailed Grouse* (*T. phasianellus*) is remarkable for the narrow and pointed form of the tail. It is rather a northerly species on the American continent, being met with in the wild country to the westward of Hudson's Bay, but it also occurs in the Rocky Mountains.

The male is sixteen inches long and twenty-three in extent of wings. The ground colour is blackish with markings of rust colour and white. The female is rather smaller than the male, and mottled with black and rusty yellow. The nest is rude, and placed in the cover of some bush. The female lays from nine to thirteen eggs, which are white with blackish spots. The young are hatched about the middle of June; they utter a piping noise resembling that of chickens. From want of suitable food or some other cause, it is found impossible to rear them in a domestic state, however carefully they are attended to. These birds are very plump when in good condition, and weigh upwards of two pounds.

*Franklin's Grouse* (*T. Franklini*). This is the spotted grouse of the Rocky Mountains, and bears some resemblance to its Canadian congener. General plumage, alternate bars of black and greyish brown, very bright and glossy; head, neck, and breast nearly black, and tail entirely so, but with white spots on the upper and under coverts, and spots of the same colour on the flanks. Nest on the ground in concealment; eggs five to seven, the size of those of the wood-pigeon, and dull white. The cry harsh, resembling that of the Guinea fowl. Rather a mountaineer, and found in the north and west parts of America.

*Canada spotted Grouse* (*T. Canadensis*) inhabits Canada, the northern parts of the United States, and the north of America generally. It is a woodland species, resembling the wood grouse of Europe in some of its habits. Has a strong flavour of spruce in winter, but is better in the summer months. Nestles on the ground, but perches in trees, and takes to them for safety when alarmed. Length fifteen inches; general colour of the male black and grey.

*Red Grouse* (*T. Scoticus*). General colour chestnut brown; eyebrow notched, very elevated; caruncle on the brow crescent-shaped and scarlet. Sixteen feathers in the tail, the external ones black at the bases. Colours of the female less bright, with zig-zag black lines, and little or no red in the eyebrow. Young, bright russet with black stripes and spots. Length of the male sixteen inches; weight nearly a pound and a quarter.

Inhabits open heaths and not woods, remaining on the ground, and never perching. It occurs on the mountains of Wales and the north of England, but more plentifully in the highlands of Scotland, and in the waste of North Britain in general. They are likewise met with in the Hebrides, the islands of the Clyde, and in the bogs and mountains of Ireland; but those noticed by Buffon as natives of France, Italy, Spain, &c., seem either to form distinct species or at least varieties. Linnæus appears to have been

unacquainted with them, and Gmelin regarded them as a variety of the ptarmigan. In this country they feed on the mountain and bog berries, and, should there be none of these, on the tops of the heath. The number of eggs which the female lays is from eight to fourteen, and not unlike those of the black grouse, but smaller, in a rude nest on the ground. The young brood continue with the hen till the winter, when they unite in flocks, sometimes to the amount of thirty or forty, and are then, from their shyness, very difficult to be shot. They sometimes descend, when the winter is very severe, from the hilly tracts, in prodigious numbers. The shooting of them is a very favourite diversion in autumn by our gentry, on the Scottish moors, and their flesh is esteemed a dainty, but very soon becomes tainted, especially if the birds are not drawn immediately on being killed. Several instances are recorded of their being reared in a domesticated state. Besides the beauty of this species, the abundance of its numbers, the interesting character of the places in which it is found, and the facilities of access to them from all parts of the British islands, it possesses the recommendation of being truly a British species.

**BONASIA.** With the upper sides of the toes feathered, but not the under.

*Hazel Grouse.* Feathers on the head somewhat long; but the species is much disposed to break into accidental varieties. Upper part brown, with red, black, and white spots. Length about fourteen inches, wings twenty-one in extent. It is a mountain species, and found pretty generally in the elevated woods throughout Europe, from the Carpathian Mountains to the Strait of Gibraltar, but not in the extreme north. It roosts in thick trees; feeds on heath tops, berries, and buds. The nest is placed on the ground under a tree, or thick tuft of heath. The eggs vary from twelve to eighteen, are rather larger than those of a pigeon, yellowish white with irregular brown spots. The incubation lasts three weeks; the young run about as soon as they break the shell; and the mother calls them to her with a clucking sound. The flesh is dark outside, and whitish internally; it is much prized, and is reported to be the only viand upon which a German prince will consent to feast twice in succession.

*Ruffed Grouse* (*B. umbellus*). The head furnished with a crest; the upper part varied with brown, red, and black; the under rusty white, with brown moon spots on the breast; feathers on the scapulars enlarged, and deep azure; tufts on each side of the neck of a bright black, glossed with steel blue, and capable of being much distended. The crest and ruff are barely visible in the female. Very common in the eastern parts of America. The female breeds twice in the year; the nest among dry leaves under a tree; eggs from nine to sixteen; incubation three weeks; general food grains and fruits. In the breeding season the male makes a flapping noise with his wings, which has been compared to the beating of the drum, and also to distant thunder; but it often costs the bird his life, by betraying him to the hunter.

There are some more species or varieties in this section, but what have been mentioned must suffice as a specimen.

**LAGOPUS.** Tarsi and toes completely feathered, so as to fit the bird for enduring the greatest severity of cold in its feet.

*Ptarmigan (L. variabilis).* Ash-coloured and white in summer, almost entirely white in winter, except the tips and shafts of the primary feathers which are black, with white tips; a black spot between the beak and eyes of the male; eighteen feathers in the tail; feet covered with feathers. Ptarmigans haunt the lofty heights of mountainous countries in Europe, Asia, and America, as the Alps and Pyrenees, the Highlands of Scotland, Siberia, Greenland, Hudson's Bay, Canada, &c., descending within the range of vegetation to feed on the buds of trees, the young shoots of pines and heath, mountain berries, rhododendron, insects, &c., but returning, when satiated, and even in winter, to their almost inaccessible retreats, which are generally screened alike from the sun and the wind, and are often formed of holes in the snow. They live quietly during winter, in family parties of from six to ten individuals; but they separate and pair in June, resorting to a lower residence on the hill, and breeding apart. Each pair scratch a circular hole, of about eight inches in diameter, at the foot of a rock or bush; and the female, with hardly any other preparation, lays from six to twelve eggs, larger than those of the partridge, of a reddish-grey hue, and spotted with black. In three weeks these are hatched, and the young come forth covered with down, which is brown, black, and yellowish, on the head and upper parts of the body, and of a whitish yellow on the under. The mother defends her young with great courage and intrepidity, and hesitates not to fly on those who seek to carry them off. Contrary to what has been observed of most other gallinaceous birds, the male is assiduously attentive to his mate when breeding, roaming about the nest, frequently uttering his cry, and carefully fetching her food, without, however, taking her place on the eggs. As soon as the young are produced, the parents conduct them to a more elevated station, where their growth proceeds rapidly. A great number of them fall a sacrifice to eagles and hawks. The ptarmigans skulk under bushes or projections of the rocks at sight of these formidable invaders; but they seem not to dread the approach of man, until they have experienced his hostile power, after which they endeavour to elude his attacks. Picot de Pezou says he has watched their manners in the Pyrenees, and that they are by no means so stupid as described by Gesner, but court independence and shun danger with the sagacity that is common to animals. In some of the Highland districts their gay summer attire assimilates them to their native rocks, and their winter livery to the snow by which they are surrounded, so that they are less readily discriminated by the sportsman. They fly heavily, but run swiftly. The cry of the male, which may often be heard in the night, somewhat resembles the croaking of a frog, and that of the female that of a young fowl. In this island they occur on the summits of the Grampian ridge, and also, though rarely, on the loftiest hills of Cumberland and Wales. These birds, being naturally very shy, cannot be domesticated without very great care and attention; but rare instances are known of their breeding in confinement. The young bird, in flavour, is not inferior to that of the black cock, and the fowler has been known, even at the risk of his life, to hunt them.

*Willow Grouse (L. saliceti).* This species is found in the north of the two continents, but on different grounds from the mountain ptarmigan. We give the

following account of it from Dr. Richardson:—"The willow grouse inhabits the far countries, from the fiftieth to the seventieth parallels of latitude, within which limits it is partially migratory; breeding in the valleys of the Rocky Mountains, the barren grounds, and arctic coasts; collecting in flocks on the approach of winter, and retiring southward as the severity of the weather increases; considerable bodies, however, remaining in the woody tracts as far north as latitude 67°, even in the coldest winters. It is tolerably abundant in the sixty-fifth parallel all the year, and assembles in vast flocks on the shores of Hudson's Bay in the winter time." The species seems to be identical with the willow-grouse of the old continent, which inhabits the greater part of Scandinavia, Kamtschatka, Greenland, and Zealand, and also the valleys of the Alps. In America these grouse shelter themselves in the winter in thickets of willow and dwarf birches, on the banks of marshes and lakes, the tops and buds of the shrubs constituting the principal part of their food at that season. Denuded sandy spots are favourite resorts in the day time; but they pass the night in holes in the snow. When pursued by a sportsman or bird of prey, they often terminate their flight by diving precipitately into the loose snow, endeavouring to escape by working their way beneath the surface, which they do with considerable celerity in thick, windy, or snowy weather; they are very shy, and they often perch on the taller willows, when it requires a sharp eye to distinguish them from flakes of snow. In the breeding season they feed mostly on the berries of the *Empetrum nigrum*, *Vaccinium vitis idæa*, and *Arbutus Alpina*, which are exposed by the first thaws, and do not disappear until replaced by the new crop. At the commencement of this period they begin to lose their snow-white winter dress, the male changing first, his head and neck becoming red, and, when viewed from a distance, contrasting so strongly with the white body as to appear as if they were stripped of their feathers, and quite raw. The beginning of June is the period of incubation, and the female then moults, the delay being admirably suited to her habits, and well calculated to ensure her safety. The male puts on his coloured plumage as soon as the rocks and eminences most exposed to the sun become bare, and at a time when he is accustomed to stand on a large stone, and call, in a loud croaking voice, to the females, that hide themselves in their white dress among the unmelted snow on the more level ground. Like most other birds that summer within the arctic circle, they are more in motion in the milder light of night than in the broad glare of day. The eggs are bright or dark yellow, with chestnut-brown spots or dots.

*Rock Grouse (Lagopus rupestris)* is another species found in both continents. It resembles the ptarmigan in many particulars, but is smaller in size, or more black and brown, and less ash colour in its common plumage. It is met with in the extreme north of America, Greenland, and in Scandinavia; and is, in fact, the most northerly of the *Gallinidæ*. It breeds late in the season.

*PTEROCLES* form the last genus of the *Gallinidæ*. They are peculiar to the warm latitudes of the eastern continent, and generally inhabit waste and sandy places. Their most general characters are: the wings long, and adapted for considerable flight; the tail pointed, and the feet naked; the tarsi stout, and the three front toes short—the hind one often want-

ing. The space round the eye is generally naked, but it wants the fine red colour which appears in the grouse. The more particular characters are: the bill of mean length, compressed, slender in most of the species; the upper mandible straight in the principal part of its length, and curved only near the tip. The nostrils basal, half closed above with a membrane, and covered with the feathers of the front. The three front toes united by membrane as far as the first joint. The hind toe often wanting, or a mere rudiment, and in all cases articulated so far up on the tarsus as not to touch the ground in walking. The claws, with the exception of that on the hind toe, are rather obtuse and broad. The tail is long and wedge-shaped or pointed, the two middle feathers being often produced beyond the others. The wings long and pointed, the first quill being the longest. As there is none of the genus resident or visitant in the British islands, they have no appropriate English names; for the compounds of the word "grouse," with other epithets which have been given to them, are not applicable. The French call them *gargas*.

*P. Alchata*, the "pin-tailed grouse" of Latham, is found in the south of Europe, but only in hot and sandy places. It is yellowish, rayed with black on the upper part, with the points of the scapular feathers bluish. The lesser coverts are streaked with red and brown, and have white tips. The head and neck are ash colour, and the throat black, with a large collar of pale orange, bordered with black. The under parts are whitish. The tail-feathers are white at the terminations, and the three middle ones slender and longer than the rest by three inches. The length is thirteen or fourteen inches. They are far more numerous in the dry places of the north of Africa and southwest of Asia than they are in the south of Europe. The young are eaten, but the old birds are of small value. We can afford space only to mention one or two of the others.

*P. Tachypætes (Namaqua)* is bright red, brown, and black on the upper part; purplish on the under, and about ten inches in length. It is found in the sultry deserts of Africa, where the flocks, which are numerous, often guide the traveller to the springs, pools, and water-courses; but if the birds clear the horizon, without wheeling or halting, it is a sign that there is no water near; and a very painful sign in such a country.

*P. quadricinctus* (the "Indian grouse" of some authors) is a native of India. The upper parts are yellowish, rayed with brown and black; the coverts of the wings yellow, with a broad band of white and one of black; the forehead white, crossed at the top with a black band; the back of the head russet, with black lines. The breast rays with white and black, forming four narrow cinctures; the under parts white, with black lines; the bill yellow, and the feet and claws brown. The length of the male is about nine inches and a half. The female is smaller and paler in the colours.

*P. arenarius* (sand grouse of authors) inhabits the sandy places of western Asia and Africa, but is also found in some of the more arid spots of the south of Europe. Upper part yellowish ash, spotted with blue and yellow. The belly, thighs, under tail-coverts, and tail-feathers black; the breast reddish ash, with one black band across. Length twelve to fourteen inches. This is understood to be a migratory bird, for which the form of its wings is well adapted. Its range is

from the sandy steppes in the south of Russia, to the borders of the African desert on the Nile, and, probably, also on the Niger. The hind toe is wholly wanting in this species, but there is sometimes a rudiment of a claw or spur in, or, at least near, its place.

There are several more species or accidental varieties of these singular birds; but they differ from those that have been named in so few particulars, and the manners of them are so imperfectly known, that we shall not name any of the remaining ones. Thus we must close our very brief sketch of the *Gallinidæ*, an order of birds which, in as far as value to man is concerned, has no equal in the feathered race. It would have been pleasant to us to enter into many more details, but we trust that what has been said will be useful in itself, and lead to the desire and the attainment of further knowledge.

GALLINULE (*Gallinula*)—the "water hen." A genus of *Echassiers*, or stilt birds, belonging to the long-toed or macrodactylic division. The characters are: the bill shorter than the head, compressed, conical, and generally higher than broad at the base. The mandibles are of equal length, both compressed at the extremity, and the upper one curved at the tip. The nostrils are placed laterally in the bill, at about the middle of its length, and they are longitudinal and in part covered by membrane. The tarsi are long, and so are the toes, of which there are three to the front and one to the rear, the front ones bordered with a straight membrane. The wings are of mean length, and hollow; the first quill is shorter than the second, and the third and fourth are the longest in the wing.

It is not very easy to assign to these birds their proper place in the system. They have been united with other races by different authors, but they do not harmonise properly with any. They have been confounded with the rails, and also with the coots; but they differ from both in structure as well as in habits. Their habits are as perplexing as their generic characters. They are not, strictly speaking, land birds or water birds; and as little can they be included in any of the ordinary sections of those which are termed shore or beach birds; for these last are in general short-toed birds, fitted for running upon sand or gravel. These birds are more aquatic than the rails, but less so than the coots, for they do not launch themselves upon the water and remain at comparative rest there, though they dash along readily and swiftly both on the surface of the water and under it.

They are birds which inhabit closely by the banks of streams, rivers, and lakes, where there is abundant vegetation, consequently only in the low land or warmer parts of cold countries. At some seasons of the year they inhabit so very closely, that it has been often alleged that they migrate; but there appears to be no good ground for the allegation. If the rails and coots are separated, as they certainly ought to be, there are only two species, the common water hen and the sultana water hen, both of which are found in Europe, though the sultana is understood to be originally from Africa. These two agree in their habits, though not in their localities, or in their size and colours; and, on account of these differences, many authors have made them separate genera, restricting *Gallinule* to the common species, and calling the other *Porphyrio*. Both differ from the rails, and agree with the coots in having a horny plate or shield advanced upon the front, though not so conspicuously

as in the coots; and they differ from the coots in not having the toes with broad and lobed webs, or any thing more than a simple projection of the skin along each margin. The whole structure of the feet, and the place of their insertion, are indeed quite different in the coot and the gallinule. The foot of the coot has the oblique motion of a swimming foot, and is articulated far backward; the tarsus is flattened, so that it may be brought forward with less resistance of the water; and the body of the bird is shaped a good deal like that of the goose. The body of the gallinule is more like that of a common fowl; and though the feet are placed rather farther back than in birds which never take to the water, they are still walking feet; and the long and elastic toes enable the weight of the body to be thrown far forward. They are, in fact, feet very admirably adapted to the places which the birds inhabit—tall and matted vegetation by the banks of the waters. The gallinule is of much more robust make than any of the rails; its legs are much stouter, its toes more elastic, and the hind one especially much more produced, pointing out that it has to travel upon more yielding surfaces. The haunts of the bird, when compared with those of the species with which it has been confounded, agree exactly with the differences of structure. It is not so much in the water, or in so broad water, as the coots, and it is more so than the water rails.

THE COMMON GALLINULE (*Gallinula chloropus*) is the only British species. It is not very abundant, or at all events very frequently seen in any part of the country, but still it is pretty generally distributed both in the southern and the northern parts of the island. The general size is about the same as that of a pigeon, and the weight, when in fine condition, about a pound; but at some seasons of the year it is very lean, and weighs much less, not above ten or eleven ounces. The length from the point of the bill to the extremity of the tail is about fourteen inches, and the stretch of the wings about twenty-one inches. The bill is greenish-yellow at the tip, and reddish-white at the base. The shield or plate, which advances on the forehead, changes its colour with the season. In the breeding time it is a brilliant vermilion colour; but when the grand labour of the year is performed it changes to reddish-white. The head is rather small for the size of the bird, and it is black, with the exception of a white spot under each eye. All the upper part is dark olive-green, of very glossy lustre; and the general colour on the under part is dull leaden-grey. The crest feathers are black; those on the belly and thighs have the points dull white; and there are produced feathers streaked black and white, which grow from the sides, and hang over the flanks and thighs. These last-mentioned feathers appear to act in some way as floats when the bird takes to the water. The hem of the wing, the margin of the tail, and some of the under tail coverts, are white. The garter, or portion of the tibia immediately above the tarsal-joint, is red; but the tarsi and the toes are different shades of green and greenish-yellow, from which the bird gets its trivial name of *chloropus*, or "green foot." The toes are very long, the middle front one measuring not less than three inches from the articulation to the point of the claw; and they are very broad on their under surfaces, owing to the bordering margins being at that part.

The body is long, and has its principal cross dimension placed differently from that of those birds which

float on the water. These are generally broader than deep, and flattened on the under side, so as to present the greater base to the water, and thus float the more lightly altogether, and with the less pressure on the individual parts. The feathers are remarkably close, and their coats well supplied with down, especially on the under side; their gloss is also such that the whole bird is water-proof, or at least can resist the action of that liquid for a considerable time.

During the day it lurks among the herbage on the banks of rivers and streams of running water, preferring those that have firm banks and clear currents to those that are stagnant and bordered with ooze. In the evenings it is more active, moving about in search of its food, which consists chiefly of small animals which in those moist places come out only after the heat of day is over. It also eats seeds and other farinaceous vegetable matters. In search of these it ranges the stubble fields, and at that season gets fat, and has its flesh much better flavoured than at other times of the year.

The nest is composed of a large quantity of withered reeds and rushes, closely interwoven, and the birds are particularly careful to have it placed in a most retired situation close by the brink of water; and the female, it is said, never quits it without covering the eggs with the leaves of the surrounding herbage. Latham and Pennant say, she builds upon some stump of a tree which is only a short distance from the ground, or a shrub by the side of water: she may, no doubt, sometimes vary the place of her nest, according as particular circumstances may command, but she generally prefers the other mode of building it. She has commonly two hatchings in a season, and lays from six to eight eggs at a time. The eggs are irregularly and thinly marked with rust-coloured spots on a yellowish white ground, and are about two inches in length. The young brood remain but a short time under the nurturing care of the mother: but as soon as they are able to crawl out, they seek the water and shift for themselves. Although the water hen is no where numerous, yet one species or other of them is common in almost every country. It is not yet ascertained whether they migrate from this country to any other, but it is well known that they make partial fittings from one district to another, and are found in cold mountainous tracts in summer, and in lower and warmer situations during winter. On examination of several specimens of this bird, in full feather, they were found, like most birds of plain plumage, very little different from each other.

SULTANA HEN (*G. porphyrio*). These birds have been described as a distinct genus by several writers; and they certainly have characters different from the common gallinule, though they approach much nearer to it than the rails or coots, with both of which it has been confounded. The characters are, whether we consider the birds as a species or a separate genus: bill strong, hard, thick, conical, nearly as deep as long, and shorter than the head; the upper mandible dilated as it penetrates into the skull; nostrils lateral, pierced in the corneous mass of the bill, nearly round and pervious; legs long and stout; the toes very long in some species; the anterior quite divided, and edged with a narrow membrane; wings of moderate dimensions. These birds, like the common gallinule, reside in or near fresh waters, haunt the extensive rice fields of the south, and prefer grain to aquatic herbs, their formidable bill being well adapted to

remove the husks, and break the straws, while their legs, and very long retractile toes are equally suited to lay hold of the stalks of the plant, and to carry the ears to their mouth. They move with grace on the liquid element, and run with equal facility on the ground, or on the leaves of water plants.

Various species, or varieties of the Sultana hen have been mentioned, but there is only one which is well known; and it must serve as a specimen. This one is, the purple water hen (*Gallinula porphyrio* of Latham). The upper mandible closely identified with the skull; the middle toe clawless, and longer than the tarsus; all the plumage blue, the frontal plate terminating behind the eyes. This definition is sufficiently characteristic of the beautiful species in question, which is nearly eighteen inches long, and about sixteen high, and which occurs on the marshy banks of rivers and lakes, and in the flooded fields of Calabria, Sicily, the Ionian islands, Dalmatia, the southern provinces of Hungary, and, though rarely, in Sardinia. It feeds on grain, plants, and roots, and is partial to fruit and fish. The nest is placed in the thick herbage of flooded or swampy fields, and is composed of bits of sticks and fragments of plants. The female lays three or four eggs. The Greeks and Romans tamed and fostered this interesting bird, introduced it into their palaces and temples, and allowed it a considerable range of flight. According to Sonnini it abounds in Lower Egypt, appearing in the rice fields in May, and the following months, and sometimes breeding in the deserts. The tibia of the Sultana are naked much further up than those of the common gallinule; the tarsi are larger and very strong; and the toes are so much produced, as to bear an almost unnatural proportion to the size of the head. The body is handsome, however, and is wholly that of a land bird, so that it is probable these birds are not much in the habit of swimming.

GAMBOGIA—is the *Garcinia gambogia* of Desvauz, and the tree whence is obtained the yellow pigment called gamboge. The tree is large and handsome, the fruit is eatable, pulpy, and sweet; in the East Indies it is believed to be a provocative of appetite, and as such is much esteemed, and enters into the composition of many sauced. The resinous juices are obtained by wounding the bark, when they exude, and, becoming concrete on exposure to the air, the small lumps—the *gummi gutta* of commerce, are collected for sale. The plant belongs to the natural order *Guttifera*.

GAMMARIDÆ. A family of crustaceous animals belonging to the order *Amphipoda*, and comprising the leaping shrimps, of which the genus *Gammarus* is the type. The body is compressed at the sides, curved, and composed of a series of equal sized segments, in which respects it is at once distinguished from the true shrimps and prawns, the anterior segments of which are soldered together into a large thoracic shield or shell, and as this structure prevails likewise in the lobster and crab families, these animals have obtained the names of shell-fish, although they have no more to do with the true fishes than any other perfectly distinct group of animals which happens to be aquatic in its habits. In the shrimps, lobsters, and crabs, moreover, we perceive only five pairs of legs, but the mouth is furnished with three pairs of foot jaws. Whereas, in this family, and indeed in the other groups of sessile-eyed, hard-shelled crustacea (except the *Læmndipoda*), the body is furnished

with seven pairs of legs, attached in pairs to the seven segments succeeding the head; but the mouth possesses only a single pair of foot-jaws, so that it is quite evident not only that certain organs which, in the *Decapoda*, are mouth organs, are transformed in the *Amphipoda* into legs, but also that the part of the body which, in the former, constitutes the head, is composed of several segments soldered together. It is to the inimitable researches of Savigny (which cost their talented author his eyesight) that we are indebted for the most satisfactory demonstration of these curious analogies, which we shall have occasion to allude to more at large in our article on INSECTS. The name, *Amphipoda*, is given to the group in allusion to another leading character, namely, that of having the legs of different forms, some of them, the anterior, being claw-shaped, and the others simple. Considerable variation, however, occurs in the form of the claws, and also in the particular legs which are clawed, and it is upon these, and various other structural characters, that the genera have been formed. In the typical genus, *Gammarus* (Latreille), the four anterior legs are formed into small claws, and the upper antennæ offer a character which is unique in the order, that of having a small articulated seta at the internal extremity of the third joint. The typical species, *Gammarus pulex* (*aquaticus*, Leach), is a small leaping animal, found in great quantities in ditches, ponds, and springs of fresh water, exceedingly active, and varying much in size. Its motions are effected in a manner similar to those of the spring-tailed insects, *Podura*, by bringing the tail, which is terminated by several appendages, beneath the breast, and then letting it go with force, thus giving, as it were, continual fillops to the water, in which it resides, and by which means it is impelled forwards. Another species is much more slender in its form, and its lower antennæ are very strong, and as long as the body. This insect forms the type of the genus *Corophium*, Latreille, which is further characterised by having none of the legs provided with a large claw. It is the *Cancer grossipes*, Linnaeus, (*Corophium longicorne*, Latreille), and is about an inch long. It inhabits the coasts of various European countries, and is called *Pernys* by the inhabitants of the coast of La Rochelle, where it resides in holes, which it makes in the mud, covered with the wood-work erected by the muscle-catchers. The *Corophium* appears at the beginning of May, and immediately commences warfare against the *Nereids*, *Amphinomæ*, *Arenicolæ*, and other marine *annelida* which take up their abode in the same places. It is very curious to observe, at the rising of the tide, myriads of these crustacea swimming about in every direction, and beating the mud with their long antennæ, and turning it over, in order to find their prey. When they have discovered one of these *annelida*, often ten, or even twenty, times as large as themselves, several of them unite together to attack and devour it. They do not cease this warfare until they have thoroughly searched all the mud. They likewise attack mollusca, fishes, and even the carcasses of large animals left in the mud. They also ascend the hurdle fences inclosing the muscles, as well as upon the latter; indeed the muscle catchers pretend that they cut the threads which retain these shell-fish, so as to cause them to fall into the mud, so that they may the more easily devour them. They appear to multiply during the whole of summer, as the

females are found, charged with eggs at different periods. The wading birds and many fishes devour them in their turn. They appear to quit the coast at the end of September, and almost simultaneously, for, at this time, not a single individual is often to be found in the places where they had only a few days previously swarmed. A more extended account of the muscle fishery of La Rochelle, and of the attacks of these insects, is to be found in the tenth volume of the *Encyclopédie Méthodique*, contained in a letter from M. d'Abigny to Latreille, and from which the above details are given.

Another curious genus in this family is *Cerapus*, of which an account has been already given. Amongst the other numerous genera, we shall only notice that of *Talitrus*, Latreille, in which the upper antennæ are very short, the lower long, with the terminal division annular, and the four anterior legs not distinctly claw-shaped. The typical species is *Talitrus locusta*, which is very abundant on our sandy shores, burrowing into the sand, and, unlike the majority of the order to which it belongs, seldom or never entering the water. It serves as food to many of the shore birds, which feed upon it with avidity. The following notice of its habits by Dr. Kidd, is from the *Entomological Magazine*:—"Under the sea-wrack, were shoals of that little jumping shrimp, with a large head, which is found upon nearly every coast; on lifting up a handful of sea-wrack, they swarmed and leaped about like fleas—some of them being scarcely bigger. These little fellows are the best anatomists in the world, in a single night they will turn a small animal into a more beautifully white and clean and perfect skeleton than can be obtained by any other means. They are of all sizes, from half an inch long to no size at all."

**GANNET** (*Sula*). A very interesting and highly characteristic genus of sea birds, belonging to Cuvier's order of *Totipalmæ*, or those which have the web, or swimming membrane, extended to the entire foot, and including the hind toe as well as the three front ones. All birds which have the feet of this structure, have them turned obliquely inward, so that they have an awkward appearance when on the ground, and the birds have an ungainly and wriggling walk. They are remarkably well adapted however for rising from the surface of the water, which is an action that these birds often have to perform, as the whole of them subsist chiefly by fishing, and by dashing down from the sky on their prey, and not pursuing it in the water, as is the case with the diving birds.

The following are the characters of the genus: the bill straight, slightly compressed, pointed, and a very little arched at the point; the edges are lined with small teeth, which are inclined backwards like barbs. The nostrils are nearly closed, and capable of being entirely so; the throat is naked, and is covered with black skin, which also extends round the eyes, has much the appearance of Indian-rubber, and like that substance is very extensible; the claw of the middle toe is toothed like a comb; the wings are long, though perhaps not so much so in proportion as they are in some of the entire-footed birds, which range the wide and fertile expanse of the tropical seas. They are timid birds, and peaceable and inoffensive in their manners; and they are at the same time heedless of the approach of danger. On this account they have had such names as "fools," and "boobies," bestowed upon them; but all such epithets given to

animals are absurd; *man* is the only member of the animal kingdom that is, or that can be, a fool.

There is only one species known in the British seas; and that is the only one of which the characters are ascertained with any thing like accuracy, and to which the name "Gannet" applies. To it, therefore, our present notice must be chiefly confined.

The common Gannet (*Sula Bassanus*), which is also called the Solan goose, (which is only an incorrect pronunciation of "Sula goose," the name of the bird on the coast of Norway and in the Faroe islands,) is remarkable for the vast numbers in which it assembles on some parts of the British shores during the breeding season. The lofty rock of the Bass in the Frith of Forth, Ailsa Crag in the Frith of Clyde, and many of the detached rocks and lofty headlands along the northern and western parts of Scotland are so thronged with these birds in the season, that they appear as if covered with snow.

The full grown gannet weighs about seven pounds; it measures about three feet in length, and six feet in the extent of the wings; the bill is nearly straight, except towards the point, where it declines a little, and is about six inches in length; the edges of the mandibles are a little jagged irregularly and sharp; the colour dirty yellowish white; near the base of the upper mandible is a sharp process and suture, which enables the bird to move it a little in the act of swallowing large fish; there are two longitudinal grooves along the sides, running the whole length, but no nostrils; the irides are pale yellow; the skin is bare round the eyes and of a bluish colour; the chin is of a dusky colour, destitute of feathers, capable of great distension, and forming a kind of pouch; except the crown of the head which is buff colour, the whole plumage is white; the tail feathers are strong and pointed, and twelve in number; the bill is of a bluish grey colour, when alive; the legs are of a dusky colour, singularly marked, with the front bluish yellow, which divides at the feet, forming a line of the same colour; along the ridge of the two front toes, the united membrane is unusually strong, and almost as transparent as glass.

The northern regions of the two continents are the chief haunts of this species. Individuals are observed in hard winters, on the coasts of England, France, and Holland, but they breed abundantly on the Bass island, in the Frith of Edinburgh, on Ailsa, off the coast of Ayrshire, the Sketting isles, on the coast of Kerry in Ireland, the islands of St. Kilda, Shetland, Orkney, Faroe, &c. In the summer season the rocks of St. Kilda are quite covered with these and other sea-birds, and appear at some distance like hills covered with snow. In the Orcadian and Shetlandian seas, although common, the gannets of that range chiefly breed on the stack "Sula's Skerry." In those districts which we have just mentioned, the gannet arrives in March, and remains till September; nor is it known in this hemisphere to breed much further south than the coasts of Scotland. Some few of them remain about their breeding stations all the winter, but they are supposed to be the old ones, which are unequal to the distant flight undertaken by the others. They do not depart or arrive all at the same time. A few of the forerunners are first seen about the Bass; and a short time afterwards the main body follows in several successive divisions. As this bird must, previously to taking wing, let itself fall, it requires a steep and precipitous breeding place. From

a considerable height it observes its prey, and darts upon it with amazing velocity and force : its nest is a rude and large assemblage of all sorts of materials, as it lays hold of any thing fit for the purpose, whether on the land or floating on the waters, as grass, sea-weeds, shavings of timber, shreds of cloth, and frequently articles picked up at a very considerable distance, or else from the nests of its neighbours. The female lays two eggs, but occasionally only one, which are white, of a rough surface, a long shape, and remarkably small for the size of the bird, being scarcely larger than those of a duck. The male and female incubate, and by turns go out fishing. It is reported currently, though erroneously, that they not only hatch their solitary egg by means of their foot, but that they place it on one end in such a manner, that if a person overturn it, he cannot make it stand as before. Dr. Harvey, the celebrated naturalist, who visited the Bass, and has described it in very elegant latinity, strangely enough asserts the latter circumstance. Under their bill, in the dilatable skin, these birds can fetch four or five herrings at a time, besides sprats, which the young extract from the mouth of the parents, with their bill, as with pincers. The young are begun to be taken in August, and are relished by some as a delicate morsel, but the older ones are tough and rancid. The fowler who seizes the young, is often let down by a rope, from the top of a cliff, and is sometimes stationed on the slippery projection of a rock, with a perpendicular precipice of more than 400 feet beneath him. About New Holland and New Zealand, gannets are said to be met with in great abundance. On the coast of Newfoundland they also breed, and migrate southward along the American shores, as far as South Carolina. They unite in small flocks of from five to fifteen in number, when they pass from one place to another; and except in very fine weather, they fly low near the shore, doubling the capes and projecting parts, and keeping nearly at an equal distance from the land. They rise high into the air during their fishing, and sail aloft over the shoals of herrings and pilchards, much in the same manner as kites. When they observe the shoal thickly crowded together, they close their wings to their side, and precipitate themselves head foremost into the water, dropping almost like a stone. In this act they never fail to rise with a fish in their mouth, their eye being so correct.

The following account given by the late colonel Montagu, of the habits and structure of the gannet, is interesting as among the most circumstantial that has been published, more especially as the veracity of the narrator is above all question : "A gannet," says colonel Montagu, "was brought to us alive on the twentieth of March, in the year 1807; it took no kind of food for seven days; it was then crammed with both fish and flesh, and soon after began to devour all white fish greedily, but did not choose to pick up even a plaice when the back was uppermost. It was remarked, that when the bill was held so as to close the mandibles for a considerable time, respiration became laborious, there being no nostrils. When the bird was placed on the water of a pond, nothing could induce him to attempt to dive; and from the manner of his putting the bill, and sometimes the whole head under water, as if searching for fish, it appears that their prey is frequently taken in that manner. It is probable more fish are caught in their congregated migrations, when the shoals are near the surface, than

by their descent upon wing; for the herrings, pilchards, mackerel, and other gregarious fishes, cannot at that time avoid their enemy, who is floating in the midst of profusion. In the act of respiration, there appears to be always some air propelled between the skin and the body of this bird, as a visible expansion and contraction is observed about the breast; and this singular conformation makes the bird so buoyant, that it floats high on the water, and does not sink beneath the surface, as observed in the cormorant and shag. The legs are not placed so far behind as in such of the feathered tribe as procure their subsistence by immersion; the gannet, consequently, has the centre of gravity placed more forward; and when standing, the body is nearly horizontal like a goose, and not erect like a cormorant.

"Having, by the dissection of a specimen of the gannet for preservation, noticed the slight and partial adhesion of the skin to the flesh of the whole under parts of the body, we availed ourselves of the opportunity of paying more attention to the structure of this bird, and, by experiments, endeavoured to discover to what extent, and upon what principle, the inflation of the body was performed. The appearance of so singular a conformation, brought to recollection what Buffon relates of the pelican; who remarks, that from the lungs the air passes through auxiliary pipes into a thick vesicular cellular membrane, that covers the muscles and envelopes the body. The structure, however, of the gannet, although probably intended for similar purposes, is very different from that of the pelican, according to the relation of that naturalist. The bill of the gannet differs from that of most birds, for it is not only destitute of nostrils, but on each side of the upper mandible, towards the base, is a dentation that divides the margin, and thus admits of considerable motion. It has been customary to describe the gannet as possessing a large pouch, like the pelican, under the chin, capable of containing five or six herrings; but this is erroneous. The gullet (*oesophagus*) is extremely capacious, and the skin, from the chin downwards, extending along the neck, is equally capable of dilation, so that five or six fishes, equal in size to that of a herring, might be contained in the gullet and stomach; for there appears to be very little difference between them; or, in other words, the stomach is a continuation of the gullet (*oesophagus*), with little or no stricture or division.

"It is well known that many birds regurgitate with much ease and facility; and that instinct points out to them the necessity of preparing the food intended for the nourishment of the young in the receptacle, usually termed the craw: in this manner the gannet, having none, can readily disgorge the contents of its stomach to satisfy its young. By comparative anatomy it has been clearly demonstrated that birds in general are provided with air vessels in different parts of the body, and that many of their bones are not destitute of this contrivance, admirably fitted for increasing their levity, and consequent buoyancy, as well as progressive motion through that element in which they are intended principally to move; and that, too, with a velocity that far surpasses all other parts of animated nature. Mr. John Hunter (in the Transactions of the Royal Society) proves that the air-cells, in the parts already mentioned, have a free communication with the lungs, by means of openings on their surface, through which the air

passes readily into them : and it clearly appears there is no *diaphragm* that confines the air to the regions or cavity of the breast, but that the whole of the abdomen is equally inflated by inspiration through the lungs. Thus far have the scientific researches of that anatomist contributed to our knowledge on this subject. No one appears to have noticed the phenomena attendant on the construction of the gannet, or to what further extent this circulation of aerial fluid is carried in some particular species of birds ; a circumstance which demands our highest admiration, when we contemplate the advantages of such a structure, in conducing to the comforts, and perhaps to the very existence, of these kinds of animals.

"Several gannets having been subjected to artificial inflation, we shall state the result, and relate the manner in which the experiments were pursued. A pipe was first introduced into the wind pipe (*trachea*), and when air was propelled through it, the whole internal cavity of the body was inflated, but no air passed into the external cells between the skin and the body. An incision was then made into the lower part of the abdomen into the body, very near the vent, into which the air was forced through a pipe ; the pipe in the windpipe (*trachea*) having been previously stopped, and a similar inflation ensued, without affecting the exterior cells. The pipe was now removed from the windpipe (*trachea*), and upon the air being propelled with force through the pipe near the vent, it readily found its way through the *larynx*, producing a noise similar to the sound emitted by the living bird. A small opening was then made in the skin, on the left side, about midway between the wing and the thigh, and a pipe introduced, having stopped first those directly communicating with the internal parts. It was now obvious that when air was forced through this orifice, the skin on that side, as far as the middle line of the body, was greatly inflated, extending into the lower part of the neck, along the larger joints of the wing, down the thigh, and also into the cavity of the body ; but the right side was not in the least affected. The pipe at the *trachea* being now removed, the air produced a similar effect upon the *larynx*, as before mentioned, but not so loud. Still suspecting that there was a communication between the sides, by means of some valvular apparatus, the right side was subjected to the same experiment ; the result, however, negatived our expectation, the effect produced being similar in every respect.

"From a repetition of these experiments upon several subjects, it became evident that there was a communication between the lungs and the cellular membrane that covers the greater part of the body, as well as with the whole cavity of the body, but that, on account of some valvular contrivance, the skin could not be artificially inflated through the lungs, although air would readily pass in a contrary direction. It is also clear that there is no direct communication between the sides. In order to examine this extraordinary structure, we made a longitudinal incision the whole length of the body, a little on one side of the keel, or what is commonly termed the breast bone ; by this means the membrane that connects the skin to the body, and cuts off the communication between the sides, was easily examined ; but nothing was observed indicating that a communication could be effected, even at the will of the bird. On each side, nearly equidistant between this pectoral membrane and the back, is situated another

longitudinal one, very similar to the last, but perforated ; between this and the pectoral are about nine irregular transverse membranous septa, that hold the skin firmly to the body, having a free communication with each other. The skin is also furnished with a transparent cellular membrane, the cells being regularly perforated close to the base of each feather. At the upper part of the breast is a large bag, which extends some way up the neck ; this is attached to the skin by the septa of innumerable small cells, but no opening into this cellular bag could be discovered ; the introduction, however, of a small pipe through an artificial aperture, clearly demonstrated a passage to the lungs, as the whole internal cavity of the body was inflated, and the air issued from the *trachea*. Upon opening this bag, the passage of communication with the internal parts appeared to be under the shoulder-blades (*clavicles*), as a thin perforated membrane was perceived at the bottom, leading to the thorax, not directly into the lungs, but near the part where the *trachea* divaricates, and afterwards communicating with the lungs. It could not, however, be discovered where the air could find a passage from the great magazine into the cellular bag, and yet there is every reason to conclude that at this part some valvular passage must exist.

"Pursuing our researches, we observed at the bottom of each lobe of the lungs a considerable opening for the passage of air into the cavity of the body. But what arrested our particular attention was a wonderful provision of nature for the protection of the vital parts, by guarding the *viscera* with a strong integument that preserves them in a proper degree of moisture, and contributes to the due secretions for lubricating those parts, so essential to the functions of their delicate nature, which might otherwise be too quickly carried off, by the constant circulation of fresh air that nearly surrounds them ; for this integument is held only by ligaments to the back and front, leaving all other parts free for inspired air. The liver and intestines are firmly attached to the surrounding integument ; the heart is enveloped by a similar covering, which is only partially connected to the common one. In the *trachea* nothing very remarkable occurs, except two small glands, about the size of a pea, at the lower extremity. The tongue is so extremely diminutive, as scarcely to be entitled to that denomination. The *clavicles*, or what is commonly called the merry-thoughts, which are usually affixed to the point of the keel of the breast-bone by a ligament, is in the gannet so firmly united as to appear a part of it. From what has been already observed, it will not be unreasonable to conclude, that the gannet is endowed with such singular properties, for very different purposes than those of long and continual immersion, of which we have before stated it appears to be incapable. But such a power of inflation must contribute greatly to lessen the concussion in its rapid descent upon water, in order to seize its prey. Besides, as the enlargement of the surface, without materially adding to the specific gravity, must greatly contribute to its buoyancy, both in air and water, it is well adapted for residing in the midst of the most tempestuous sea, floating on its surface in perfect security, and following those shoals of fishes on which depends its whole existence. Thus, when all other birds are compelled to seek shelter in bays and creeks, the gannet is enabled to

brave the severest weather in all seasons, without attempting to near the shore.

"This contrivance may also be of the most important service to an animal which is constantly exposed, even in the most inclement seasons, and cannot quit its station without starving. Nothing could possibly conduce more to its security against intense cold, or be better adapted to preserve the necessary temperature of animal heat, than the intermediate air dispersed between the skin and the body, since that element is found to be a non-conductor of caloric. Upon this principle, what animal can be more securely protected against cold, or retain its vital heat so effectually, as the gannet, or such birds as are almost surrounded with a body of confined air, divided by cells, and intersected by membranes between the skin and body, and that skin so amply covered with a light porous substance, filled also with air, and impervious to water? The gannet is capable of containing about three full inspirations of the human lungs, divided into nearly three equal portions, the cellular parts under the skin on each side holding nearly as much as the cavity of the body. Now, as a full or extraordinary inspiration of the human lungs has been considered to occupy a space of about sixty cubic inches, so the gannet is capable of containing not less than one hundred and eighty cubic inches of air at one time, subject to the will of the bird, under certain impressions."

The following account of this very singular organization of the gannet, which, though possessed in common with the cormorants and some others, is yet so much more remarkable in the gannet as to be deserving of particular attention, is from the observation of Messrs. Owen and Yarrell, read to the Committee of Science of the Zoological Society in 1831. "In the examination," say these able comparative anatomists, "our attention was chiefly directed to the air-cells, which, in this bird as in the pelican, have a most extensive distribution. We commenced by gentle but continued inflation through the *trachea*, a pipe having been introduced into the upper *larynx*: in a short time the integuments of the whole of the lateral and inferior parts of the body rose, and the air-cells seemed completely filled, especially that which is situated in front of the *os furciforme*. Being thus satisfied that they all had a free communication with the chest, we next proceeded to see at what points these communications took place, and in what degree the air-cells communicated with each other. For that purpose the air-cells on the left side of the body were laid open, and shortly after those of the opposite side collapsed, indicating the existence of apertures of communication, although the *septum* which ran along the middle line of the body appeared at first sight imperforate. There was a free communication between the lateral air-cells of the same side of the body from the *os furciforme* to the side of the *pelvis*; but the air-cells in front of the *os furciforme* remained still tensely inflated. The lateral air-cells had a free communication with the cavity of the chest at the *axilla*, at which part the air had entered these cells during the inflation. The pectoral muscles and those of the thigh presented a singular appearance, being, as it were, clearly dissected, having the air-cells extended above and below them; the axillary vessels and nerves also passing bare and unsupported by any surrounding substance through these cavities. We traced the air-cells down the side of the *humerus*,

ulna, and metacarpal bone, into all of which the air entered, and even into the bone corresponding to the first *phalanx*, which agrees with what Mr. Hunter has described in the pelican. As none of these proceedings had any effect on the air-cells in front of the *os furciforme*, which still continued distended, it was evident that inflation by the *humerus* could not have filled it, except through the medium of the lungs themselves. We next proceeded to detach the integument from this air-cell, to see its shape and extent; this required to be done with great care, as it adhered pretty closely to the skin and roots of the feathers: it was of a globular form, about four inches in diameter, and communicated with the *thorax* at its anterior aperture below the *trachea*. Numerous strips of muscular fibres passed from various parts of the surface of the body, and were firmly attached to the skin; a beautiful fan-shaped muscle was also spread over the external surface of the air-cells anterior to the *os furciforme*. The use of these muscles appeared to be to produce instantaneous expansion of the air from these external cells, and by thus increasing the specific gravity of the bird, to enable it to descend with the rapidity necessary to the capture of a living prey while swimming near the surface of the water. With respect to the general anatomy of this bird, it may be observed that we found the two glands at the termination of the *trachea*, which are noticed by Montagu, and which exist in addition to the ordinary pair lying above the *bronchie*. The stomach corresponded exactly with the figure given by Sir Everard Home (Comp. Anat., p. xlv.), the pyloric orifice being provided with the bilobed valve, which is there represented, though not described in the text; it evidently opposes a too ready egress of the contents of the stomach."

We have given these observations in the words of the observant authors, and we shall not point out the small discrepancies which might perhaps be found, upon examining what those first quoted have said, with an eye of severe criticism. The fact is, that there is no part of the animal structure of the real use of which we know less, than of that power which some animals have of inflating their bodies in whole or in particular parts. The air under the skin of the thorax in the gannet must render the whole body of the animal more buoyant, and as little can there be any doubt that it can take off the concussion which the bird would otherwise experience when it plunges down from a height upon its prey; and that it has some pretty severe labour to perform, is almost a necessary inference, from the strength of the skin and its internal membrane, and the number of points at which it is tied to the muscles, the keel of the sternum, and other parts. But it is rather too much to assume that this apparatus has any thing to do with the preservation of temperature in the bird. There is no such provision in the whole animal kingdom. If dry cold is to be guarded against, that is, cold in which water does not reach the skin, then fur and down are the provisions; and if moist cold, the protection usually consists of a layer of fat under the skin, the latter theory of its action is what is most likely; and when we consider what injury the human body may receive by plunging into water from a height of not more than twenty or thirty feet, we can at least guess at what the gannet encounters, when it not merely falls, but shoots down with an impetus from more than ten times the height. The gannet always

meets the water with the breast in its plunges, because the head penetrates with little resistance; and the elapsed time between seeing the prey and seizing it must be the least possible. Altogether the gannet is far more a bird of the mere surface of the water than any other of the entire-footed birds which plunge down upon aquatic prey. Altogether it is one of the most interesting of our shore birds, both in its own appearance and habits, and in the character of those places where its countless myriads take up their abodes. No one should visit the wilder parts of our shores without some previous knowledge of the gannet. The gannet is eaten, but it is both tough and rank. In some places it is eaten in order to whet the appetite, in which case it is salted and smoked.

The Common Booby (*Sula communis*) is not so interesting a bird as the gannet. It is larger than a common duck, but less than a goose. Its body is greyish-white, with black tips to the quills, and the tail brownish; but it is very subject to varieties of colour. It ranges over the whole Atlantic, from the confines of the polar ice to the equator. It is a very fearless bird, and so familiar, that if it is fatigued by being long on the wing, it will alight on the hand, and allow itself to be taken. It is, however, pretty safe from the effects of human cupidity; for its flesh has so rank a taste, that men must be reduced to the greatest extremity before they can prevail upon themselves to eat it.

**GARCINIA** (Linnæus). A genus of beautiful fruit trees, natives of Malaya and the neighbouring isles. It belongs to *Dodecandria monogynia*, and to the natural order, *Guttifera*. Generic character: calyx of four sepals, persisting; petals four, roundish, concave; stamens seated below the germen, nearly united at the base; anthers oval; style none; stigma from four to eight, lobed; berry four, six, or eight celled; each containing one seed.

The *G. Mangostana*, or *mangosteen*, as it is frequently called, is one of the choicest fruits, being the most delicious, and, at the same time, the most wholesome. It is about the size, and has much the appearance of a large pomegranate, consisting within of a soft, transparent, juicy pulp, in which the flavour of the grape and strawberry are combined. The plant is in our stoves, where it grows freely in light loam and moor earth, and kept in a strong heat. Ripened cuttings strike roots in sand under a glass, in moist heat.

**GARDEN BALSAM.** is the *Balsamina hortensis* of Rivinus, formerly the *Impatiens balsamina* of Linnæus. This is a well-known ornamental plant. They are raised annually from seed sown in a hotbed in March, and afterwards placed and nursed in pots till they flower.

**GARDENIA** (Linnæus). A genus of beautiful evergreen shrubs, natives of China and other places in the east. Class and order *Pentandria monogynia*, and natural order *Rubiacea*. Generic character: calyx, in five divisions; corolla, salver-shaped, tube cylindrical, segments of the limb oblique; anthers, sitting; stigma, two-lobed; berry two celled; seeds in several series. This genus is much valued by collectors; their beautiful white flowers and rich scent, particularly the double and single *G. Florida*, are among the choicest of Chinese plants, and much care is bestowed in bringing them into flower. They are propagated by cuttings.

**GARLIC**, is the *Allium sativum* of Linnæus, a well-known culinary plant. See **ALLIUM**.

**GASTERIA** (Haworth). A genus of succulent plants, natives of the Cape of Good Hope. The flowers are hexandrous, and the genus is arranged in the natural order, *Hemerocallidæ*. Generic character; corolla tubular, nectariferous at bottom, limb regularly six cleft, or somewhat gaping; stamens inserted into the receptacle; anthers oblong and incumbent; style simple; stigma three-lobed; capsule three-celled, three-valved, with a central placenta; seeds three-sided, or compressed and winged. These plants were formerly associated with the aloes, but have been separated by Duval and Haworth. They are grown in sandy earth and lime rubbish, and require but little water, as their leaves are very thick and fleshy.

**GASTEROPHILUS** (Leach). A genus of parasitic dipterous insects inhabiting the stomach of the horse, belong to the family *Estridæ*; the grubs or larvæ of which are ordinarily termed Bots. See the article Bot.

**GASTEROPODA.** Lamarck's fourth order of molluscs, including all the animals, having straight bodies, never spirally formed, or entirely concealed in a testaceous covering. They possess a muscular disc under the belly, attached to the body, nearly its whole length, which acts as a foot in progressive motion, and gives rise to the name of the order.

**GASTROPTERA** (Meckeli). A naked mollusc, whose body appears divided into two parts, the posterior globular, merely, as it were, connected by peduncles to the anterior, which is very small, enlarged on either side into a large muscular expansion, transversely oval, slightly grooved backward and forward, which renders it as if bilobed, and, acting as a foot, serves for the purpose of swimming; the lateral bronchia are altogether exposed. It is found in the seas of Sicily, and is probably the species described by Rafinesque, under the name of *Sarcopterus*—meaning fleshy wings. *Gasteroptera* means wings on the belly. Those naked molluscs, occupying formerly a separate existence in the system of natural history, almost totally unconnected with shell-bearing molluscs, presented no interest beyond the wonderful and beautiful organisation they exhibited; by the present combination of them in the general arrangement of Malacology, they serve as illustrative links, which prove, beyond all manner of doubt, the propriety of adopting a system based upon the immutable wisdom of Nature's architect. The French naturalists have placed this genus in the fourth family, *Akera*. Third order, *Monopleurobranchiata*. Second class, *Paraccephalophora*.

**GASTRODHÆNA.** A genus of Molluscs, established by Spengler; the shell is equivale, somewhat wedge-shaped; the anterior opening oval, oblique, and very large; the posterior one nearly closed; the hinge is linear, without teeth, and marginal. This mollusc penetrates hard substances in the manner of the pholas. It seldom exceeds half an inch in length, and inhabits the British coasts.

**GAULTHERIA** (Linnæus). A genus of small evergreen shrubs, natives of North America, Nepal, and New Zealand. The flowers are decandrous, and belong to *Ericæ*. The *G. procumbens* is a very common plant in American borders, requiring a moor-earth soil, where it propagates itself abundantly.

**GECARCINUS** (Leach). A genus of land crabs, belonging to the *Decapod Crustacea*, and section *Quadrilateres* of Latreille, having the body somewhat square, the third and fourth pair of legs longer than the second and fifth, and the antennæ concealed by the front of the carapace or shell; the second and third joints of the outer foot-jaws are large, flattened, and curved. The typical species is the *Cancer ruficola*, Linnæus, a native of the West Indies, and generally known under the name of the violet crab, or *Tourlourous* of the French. They reside in the mountainous districts, but as soon as the rainy season sets in, in May and June, they make their way to the sea, in order to deposit their spawn in the water, in such vast numbers that the roads are covered by them. They resemble a vast army marching in battle-array, keeping steadily onwards in a direct line, without allowing any obstacle to impede their steps, scaling even the walls of houses which happen to be in their route, and travelling chiefly by night. When arrived at length at the sea-shore, they are much enfeebled, and dash into the water with great eagerness, which they repeat several times; they then retire to some neighbouring wood or other covert, and, in a short time afterwards, the females again return to the water, and commit their eggs to the waves, which are alive with fishes waiting for this annual treat, and by which a very great deal of the spawn is devoured. The crabs then return to their old quarters by the same route, but this, in their still enfeebled state, is a difficult task. When arrived there, however, they have to undergo another annual labour, namely, that of moulting, and which takes place in their subterranean burrows, the mouths of which, it is said, they close. See further the articles CRAB and BRACHYURA.

**GECKOIDÆ, GECKOS** (*Ascalabota*). The fourth family into which Cuvier divides the saurian or tailed reptiles. They are, strictly speaking, the nocturnal lizards, and they may all be included in one genus, though the species, which are very numerous, differ from each other in so many particulars that they admit of arrangement into several sub-genera. Their relations to the other families of the order and orders of the class will be found detailed in the article REPTILE, in its place in the alphabet.

Their form is not so light, nor their motions so volatile, as those of the true lizards. They are flattened, especially in the head, which gives them a heavy appearance, and their motions are dull and crawling. Their feet are of mean length, or rather short, and their toes are of nearly equal length, and often peculiarly formed. As is the case with all nocturnal animals that seek their prey chiefly on the surface of the earth, their eyes are very large, and the pupils close on vertical lines as in the cat. Their eyelids are small and drawn in between the eyeballs and the orbits, which gives them a very singular appearance. Their tongue is fleshy, and not extensible beyond the mouth. Their jaws are furnished each with one row of teeth, very small in size and closely set; and they have no teeth on the palate. Their skins are covered with small granulated scales, like shagreen, but these are interspersed with larger tubercles, and the scales on the under part are generally of a larger size and imbricated. Some of the species have pores upon the thighs, and others have not; the tail has circular plaits or folds, as in the genus *Anolis*; but when it is once broken

off, the new tail which grows in its place is destitute of folds, and also without tubercles in those species which have the original tail tuberculated.

Reptiles of this genus inhabit the warmer regions of both continents, and the species are very numerous. The appearance of these animals is peculiarly loathsome; they not only inhabit places which are dark and obscure, but those which are rank and offensive; and as they bear no inconsiderable resemblance to toads and salamanders, they have had the stigma set upon them of being venomous. That it poisons by stinging or biting, or any other species of offensive apparatus, or instrument of attack, is not true, and cannot be true, of any species of gecko; for none of them possesses a sting of any description, and the teeth in all are so very minute that they are incapable of penetrating the skin of any animal of moderate size. That some of them discharge a poisonous liquor is, however, well understood, but this liquor is discharged from pores in the feet; it is of so very virulent a nature as to inflame or even blister the skin when they run across it; and it is particularly dangerous to those who have eaten any provisions over which these animals have passed. The poison of the geckos appears, therefore, to be very similar to the poison of some species of toads; being in both an exudation from the skin, and not appearing to be, generally speaking, a means of capturing their prey, or of attacking any other animal, as is the case in animals which have stings or poison fangs. This circumstance, together with the toad-like aspect and clumsy gait of these creatures, is in all probability the reason why they are looked upon with so much aversion by most people; and this is, no doubt, also further increased by the foul places in which they reside, and their nocturnal habits.

Offensive as they are, however, they are not entirely useless, even in the domestic economy of those places where they are most abundant. These are, as we have said, the warmer regions both of the eastern continent and of America; and if the greatest domestic cleanliness is not observed in such places, the habitations of the people are very much pestered with spiders, and also with a variety of insects, both winged and crawling. Such of the winged ones as are diurnal in their habits are, in a state of repose, in holes and crannies during the night; and it is at this time that the nocturnal ones crawl abroad. These minute creatures constitute the principal food of the geckos, which seek after them with so much assiduity that in many places where the habits of the people are slovenly, they are encouraged for the purpose of keeping the houses as clear of the others as possible, though, according to our notions of domestic cleanliness, the cure would be considered as even worse than the disease.

The toes of the geckos are generally bordered with membranes for the whole or the greater part of their length. The under sides of them are generally covered with regular rows of small scales, the edges of which take a very firm hold of the substances over which the animal passes. The toes, with the exception of the thumb or inner toe, which is very small in some of the species, are also, as has been said, of nearly equal length; and they spread as it were from a centre, something in the same manner as the rays of a fan, from which structure they become double grasping feet, or what may perhaps be termed "crab feet," which can hold on upon very slight inequalities,

not only on the upper sides of bodies, but also on the perpendicular and even the under sides. By means of this peculiar structure of the feet, and not by suckers as has sometimes been supposed, they can contrive to make their slow march a very sure one on all sorts of surfaces where they are likely to find their food. They can crawl up the walls of houses, and also along the roofs and ceilings with their backs undermost, though it is possible that in the latter case they are assisted by the peculiar structure of their claws; and yet the mechanism of those claws would lead one to suppose that they are used for other purposes. They are hooked and very sharp at the points, and also retractile, something after the manner of the claws of cats, so that in the ordinary march of the animals they do not touch the ground. This renders it probable that their points are preserved in order that they may assist in some way in capturing their prey; and it is at least possible that the acrid liquor with which the feet are provided may assist in this operation; but this point, like the habits of the animals altogether, is not a little obscure.

The peculiar structure of the feet in the geckos renders it very doubtful whether any animal, at least any vertebrated animal, makes use of suckers upon the feet as a means of progressive motion. The mechanics of nature, though in every respect superior to the mechanics of human art, never violate any well established law of mechanical action. It is not indeed to be expected, or indeed to be believed, that they could in any way do this; for our laws of mechanics, as established from experiments on dead matter, are not only of the same class but perfectly identical with the same laws as they obtain in the living world. That this must be the case may be seen by a moment's consideration. The living animal, or if the expression be preferred, the principle of life in an animal, has to contend with exactly the same kind of difficulties, and overcome exactly the same kind of resistances as we have in our mechanical operations. The properties of matter, considered as such, are the same in both cases; and there is much less difference between an animal balancing or suspending its whole body or any particular part or organ of it and one balancing or suspending any piece of matter, than would at first be supposed. The doctrine of the centre of gravity, and the combination of pressures and resistances, are the same in the one case as in the other; and the only difference consists in the superior construction of the animal's apparatus, and a greater certainty with which that apparatus can be applied.

This is a very beautiful, and far from an uninteresting part of the science of natural history; and if the describers of the actions of animals had always been well informed in those mechanical principles, which have been established by experiment or by mathematical demonstration, before they had proceeded to their professional labours as naturalists, the books on this most interesting subject, in its most interesting branch, would not have been so replete with error and absurdity, and assumption in violation of all mechanical principle, as we too frequently find them.

We are distinctly to understand then, that the labour which an animal has to perform by means of the structure of its body, is precisely the same in kind with that which we have to perform, in balancing, supporting, and moving from place to place, those pieces of matter which we do so act upon,

either as parts of our machinery, or for other purposes. But between us and our machine considered on the one hand, and the life and organisation of the animal considered on the other hand, there is a very remarkable difference. Our materials and our art are separate from each other; and we have to learn the means of using from the nature of the thing used and the use intended. We never can be sure how far even our best information may fall short of what there is to be known respecting any one material, and therefore our very best art is a second rate species of bungling, as compared with that displayed by the most apparently simple and humble animal. The reason is, that in the animal the living principle elaborates its own organ, or at all events the two originate and come to maturity in so close union with each other, that we cannot separate them even in imagination. If we see even a detached part which we believe to have once belonged to an animal, as a bone, a shell, or any thing else, even though that bone or shell remains only in form and the substance has become a species of stone, or a petrification as we call it, we can no more refer that remain to any other than an animal organ, than we can say that a block of granite or a bar of iron is a product of life, or remain of some strange animal of antediluvian years.

Carrying this principle with us, and viewing the peculiar structure of feet and the ordinary rate of motion in the geckos, we can hardly fail in feeling some doubt as to the accuracy of the common motion of animals, and those, generally speaking, much swifter footed animals securing their footsteps by means of suckers. This is tolerably well made out by the analogy. The placing of the sucker so as that it would lay hold, and the removal of it again after the hold is taken, requires some time, as we may perceive in leeches and animals which usually perform their march by means of suckers, when they are out of the water and incapable of swimming. The sucker is never in them a point of momentary rest, from which they are thrown by an impetus of recoil, in the same manner as a walking animal is thrown into progressive motion by the recoil of its feet touching the ground. The posterior sucker serves as a point of resistance, from which the whole body of the animal is pushed forward by being elongated, and this takes some time, so again the anterior sucker is an instrument of prehension, by means of which the animal holds on until it draws up the length of the body to a very small fraction of what it previously had; and when the greatest contraction is made, and the posterior sucker again fastened, the anterior part of the body is again advanced, and the motion is continued by those curious steps as long as the necessity of the animal may require, or its ability admit. Nor do we know any fully established instance in which suckers are used as even fulcrums of motion, except by annulose animals which have the power of alternately lengthening and shortening their whole bodies in order to produce motion, instead of having separate organs for that purpose, as is the case in all vertebrated animals, however different those organs may be in form, or however rudimental in some cases.

If any saurian reptile, or other vertebrated animal, were to have suckers as instruments of motion, the geckos are unquestionably the animals with whose habits, according to all that we know on the subject,

they would best agree; and we may add that, of the whole race they appear to be the ones in which such organs, if they could be usefully applied in walking, would be most essential. The march of these creatures is very slow; it is taken over many kinds of surfaces, and surfaces placed at all imaginable angles to the horizon; and as the sucker in the common descriptions of it is understood to act by atmospherical pressure, which is of course equal in all directions, it would of course be equally serviceable to the geckos, when back uppermost on the floor, back undermost on the ceiling, or ascending or descending the wall. If the sucker were the best apparatus for this purpose we may rest assured that the gecko would have it; but it has no such provision; and the rows of scales upon the under surfaces of its toes, and their marginal membranes, are quite incompatible with a perfect expulsion of the air from under the foot. It is possible, however, that those margins, whether they extend wholly or partially along the toes, may act as lateral branches of the toes, and press downward by muscular action, so as to enable the under surface of the foot to embrace more of the asperities of the surface along which the animal walks; and the scaly irregularities upon the under side of these feet are so very numerous that it would not be easy to say at how many points of a surface one foot at the same instant lays hold.

The subject of climbing, and walking, or running with the back undermost in animals which have not the power of grasping, is a very interesting one in the natural history of animals; but in this respect there is a wonderful resemblance between common naturalists, or describers of animals, and common portrait painters. They succeed tolerably well in making out a *face*—a surface and the remarkable features which distinguish one individual from another to common observation—but if there is a hand or a foot in the case they make sad work of that; and just as the face-painter's hand could not work if formed as he represents it, and the foot could not walk, even so the generality of animals could not budge an inch by means of such organs of locomotion as the naturalists in question are pleased to assign to them. It were therefore to be desired that much more minute attention should be paid to the actual structures of animals, and especially to the feet, in which the display of mechanical principle, and perfect adaptation of that principle, are not only more beautiful in themselves, but come nearer to our practical usefulness in mechanical arts than any other parts of the animal fabric. The internal operations of animals—circulation, respiration, digestion, secretion, sensation, and the others, though very wonderful in themselves, and well worthy of being studied, both as portions of general knowledge, and as means of enabling us to economise animal life, and deal kindly with it, have yet little or no application to our common arts, because we have no operation to perform, external of our own bodies, which is of the same kind with these; and our own internal operations are carried on, not only without our care, but often in spite of our ignorant and ill-directed attempts, which if they were not as futile as they are faulty, would do harm and not good.

The external actions of the animals,—those which we may regard as the uses of the structure of any particular animal in nature, are not only much more in accordance with what we are called upon to do,

but they are really our models; and many things might be mentioned which men have derived no little celebrity for contriving or inventing, which might have been discovered at once, and in far greater perfection, in the structure of the very best known animal. When we express it in words, it sounds somewhat oddly; but it is nevertheless true that if the most skilful mechanic is set on horse-back, there is really much more instruction in mechanics to be got from the horse than the man, if the student but knew the way of finding it out.

The feet of mammalia bear in many respects so much general resemblance to our own organs of motion, and prehension, that at least we believe we have some notion of them. The feet of birds are also tolerably open to our scrutiny; and though our oars and other contrivances for propelling bodies through water, are very imperfect as compared with the swimming apparatus of fishes, yet there is some resemblance. There is curious point in this resemblance, or rather, perhaps, it is a want of resemblance which is worth notice. We propel all our oared craft by a sort of lateral fins, and steer by the rudder as a sort of tail fin; while the fishes are propelled chiefly by the tail, and, in part at least, guided in their motions by their lateral fins. But to return: the feet of reptiles, and even those curious substitutes which we find in the scales and flexures of the body of those which have no feet, far more nearly resemble those machines which we use in supplement to our hands, than the feet of the higher orders or vertebrated animals. Hence they are far more deserving of our study with a view to the perfection of art; and when we notice how small and simple an apparatus in these animals suffices for the accomplishment of a great number of purposes, we cannot fail to perceive how much even our best machines must be loaded with unnecessary lumber in which mere complication of parts is often mistaken for that perfection of which it is the very opposite.

In this way animals which are so apparently humble in their sphere of life, and so repulsive to our common feelings as the majority of the gecko family are, may still be made the instruments of useful instruction, if we would but study their forms, and observe how those forms are applied in their modes of life. It is true that geckos are what we call filthy creatures: they crawl in the mud, and search for larvæ and other things, on which they feed in the most loathsome places, so that they often visit the abodes of man, or at least traverse his apartments in no very cleanly plight. They also poison provisions with the tread of their feet, as has been already mentioned; but for all this they are the workmanship of the same Author as the most elegant race upon earth; the purposes which they answer are part of the grand scheme of nature's working; and our wisdom lies, not in avoiding them as odious, but in studying them as one page, though a singular one, of the book of instruction. The greater part of the race have the toes flattened, and with enlarged margins throughout their entire length, and supplied on the under sides with regular scales and folds; but the number of toes varies; and on this as well as on other grounds they are conveniently divided into five sub-genera, of which we shall give a mere enumeration, without the details of the species, the greater number of which are merely museum ones, and as such perfectly useless in the study of living nature. These five sub-

genera are named by Cuvier, *Platydaetyli*, *Hemidaetyli*, *Thecadaetyli*, *Ptyodaetyli*, and *Spheriodaetyli*; and the last admits of some farther sub-division besides that into species.

*PLATYDAETYLI*, flat toes, have the toes enlarged at the sides for the whole of their length; and furnished on their under surfaces with transverse scales. Some of them have not claws on all the toes, and have the thumbs or inner toes small as compared with the rest. Those which have this structure of the feet are the handsomest of the family; they are beset with tubercles, and ornamented with bright colours. All the known species are natives of the isle of France: some are without pores in the groin; one species is violet on the upper part, and white on the under, with two colours parted by a black line along the flanks; others again are grey with eye-spots all over, brown at the edges, but with white centres; and others have the pores very conspicuous.

*A. Facetanus*, the wall gecko, is the species with which we are best acquainted. Its general habitat is the basin of the Mediterranean, on all the shores of which sea it is found, though more abundantly in some places than in others. It is the *stellio* of the ancients, though different from the reptiles to which modern naturalists give that name. It is known by different names in different countries; but we believe the most common one has some resemblance in meaning to the English name "toad-lizard." It is found in Egypt, in the states of Barbary, on the east coast of Spain, but not on the west of Spain or Portugal in the same latitudes. It is also found in France, in Italy, in Greece, and throughout the Levant, and is understood to be the kind of reptile which Solomon describes as taking up its abode in the palaces of kings, which does not prove much with regard to the cleanliness of royal dwellings at that period of the world's history. It is an unpleasant animal to look on; its colour is deep dull grey; its head very rough; all the upper part of its body studded over with gnarly tubercles, each of them consisting of three or four smaller ones, placed close together, and apparently running into each other. Its habits are as unpleasant as its appearance; it is a thing of the night, lying concealed while it is light, but crawling out at dusk something after the manner of a toad, searching for flies and other creatures on which it feeds, with its curious cut-like eyes, and probably using its crooked claws to assist in their capture. Deserted houses, neglected corners, mouldering ruins, and all places which in consequence of man's neglect are rank with impurities, and consequently abound in that insect food which it seeks, are the favourite haunts of this creature. And it appears to have borrowed not a few of the gloomy circumstances which are connected with the times and places of its appearance; for it has been very generally set down as one of the most pestilent of creatures, and one which it was a charity even to nature to destroy by every possible means. In this case it has fared much the same as the toad has done, which, like the wall gecko, is no beauty, though it is a very useful scavenger, tending not a little to the destruction of creatures which would taint the air, and thereby contributing more to man's comfort than some of the animals which he cherishes with the fondest admiration.

It gets its name from the facility with which it can ascend the walls of houses, and pass along the roofs and ceilings; and in some parts of the countries which

it inhabits, it is found very useful in clearing the houses of mosquitoes and spiders. There appear to be several varieties of this species, or at all events several species closely allied to it in habits, though they differ a little in some of their external characters. Of these may be mentioned one found in Egypt and Barbary, which has the tubercles entire and round, and more prominent on the flanks than any other part of the body. All these varieties are equally harmless as to attack; but they are all equally offensive in their manners, and it is understood that they all distil from the toes that acrid liquor, which has been described as poisoning provisions, though this property is perhaps stronger in some of the others, and probably this one has the liquor more acrid in the warmer than in the colder places of its abode.

*A. gecko*, the gecko, is an Indian species, and is the one upon which the name gecko is founded, which is described as being as nearly the sound uttered by the animals. This species has no thumb claws on any of the feet; it is covered with flattened and rounded tubercles on the upper part of the body, the colour of which is reddish marked with round spots of white; the lower part of the tail is covered with square scales, which are imbricated or placed over each other like tiles. It is represented as abounding in all the oriental Archipelago, but is unknown in the western part of the old continent, and in America.

*A. vittata* is another species inhabiting the same countries; its general colour is brown, with a white stripe down the back, which parts into two branches on the head, and also at the insertion of the tail; and the tail is surrounded with white rings.

*A. homalocephala*, the margined gecko, is found on the continent of India, and also in the eastern isles; its head and body are bordered with a white membrane, its tail is furnished with lobes of the same, and its feet are webbed. Other species of the same country are mentioned as having the tail without any lobes on the sides; and there are also some of this sub-genus which have claws on all the toes, and some of them are entirely without tubercles.

*HEMIDAETYLI*. This name does not mean literally that the animals are "half-toed," but simply that the expansion in breadth extends only to half the length. This expansion consists of an oval disc upon each toe, furnished on the under part with two rows of scales, in the form of a chevron, or having an angle in the middle. From the middle of this disc, the second joint of the toe rises, which is very slender, and carries the claw, which however has an articulation, thus forming a sort of third joint. All the known species of this sub-genus are described as having claws on all the fore-toes, and a row of pores near the vent; and the scales on the under side of their tails very much resemble those on the bellies of serpents.

There is one European species of this sub-genus, usually called the warty gecko, which is found in the same countries with the wall gecko. It is of a reddish colour; and the tubercles on the back are small and conical, but with blunted points. There are various species and varieties very much resembling this one in the warm parts of Asia, and some also in America, and the West India islands; but their manners are little known, and not very interesting.

*THECADAETYLI*, sheath-toed. These have their toes broadened throughout their whole length, and furnished with transverse scales; but they are divided

longitudinally by a deep furrow on the under side, the anterior part of which can entirely conceal the claw, which is the reason they are called sheath-toed. They generally speaking want claws on the inner toes only; and their tails have small scales both on the upper and the under surfaces. As an instance of this division, we may mention the smooth gecko (*A. perfoliatus*), which is found in the West Indian islands, and is there sometimes called the Banana lizard, from its being found lurking in these plants. Its colour is grey mottled with brown; its scales very small on the upper part, and without any tubercles; the tail is long, and furnished with circular folds as in many of the other species, but it is very little; and when once broken off the new one, which grows readily, is very frequently quite different from the original one, and has caused the animal to be described as being more than one species.

*PHYODACTYLI*, fan-toed, have the points only of the toes widened by marginal expansions, and these have their under surfaces marked with striæ, radiating from a centre like a fan. The middle of each is divided by a longitudinal furrow, in the end of which the claws are placed. There are claws on all the toes, very sharp and crooked. Some have the tail round, and all the toes free, or without any connecting membranes, and these are of course inhabitants of the land only. Others have the tail with margins, and the toes partly webbed, and they are probably, in part at least, aquatic. Of the former, one of the best known species is

*A. lobatus*, the house gecko. This species is rather smooth in the covering, having the scales and tubercles both very small. It is of a reddish grey colour, with small spots of brown on the upper part. It is a hideous, or, at all events, an ungainly animal in appearance, and the sound which it utters is a hoarse croaking like that of a frog. It is found chiefly on the south-eastern coast of the Mediterranean, and is peculiarly abundant in Syria and Egypt, where it has been long known, and generally disliked. It appears to shun the light of day and the beams of the sun much more than the wall gecko, and the exudation from its feet is far more pestilent than that of that reptile. Indeed, it is not improbable that the greater part of the poisoning quality which has been attributed to the other really belongs to this, and that they have been confounded with each other. The passage of the house gecko over the skin, though its feet produce no laceration, or any mechanical effect whatever, is attended with very severe pain and inflammation, which extend to other parts besides those over which the creature passes. So much is it dreaded on this account in some countries, that in Cairo it is branded with the name of *Abu-burs*, "the father of the leprosy." That it can produce the disease which is thus fathered upon it is not at all likely, though it certainly does occasion much pain and inconvenience. It is probable that this is the one alluded to by Solomon, as taking up its abode in the houses of kings, with the same confidence as the coney (the jerboa) makes its holes in the rock. The minor pests of cold countries like ours, which, where the strictest attention is not paid to cleanliness, are apt to visit us on our couches, and invade our slumbers with a more vexatious species of annoyance than that occasioned by more powerful enemies, are bad enough; and it has been said, that "the man who braves a bomb will yet tremble at a bug." These, however,

are nothing to such a nightly visiter as the house gecko. It is like Caliban's curse; it blisters the people all over, and it is as tenacious of its abode at the present day as it was in the reign of king Solomon. It is true that, in our common translation, the spider is the creature mentioned as the sure tenant of the royal palace; but, as the spider does little harm anywhere, though sometimes accused of it, and usually remains in the middle of her nets, leaving the inhabitants of even the most dingy dwellings in peace, it is more likely that this pestivorous spider-eater was the creature alluded to. There is great difficulty in expelling the house gecko, or even of finding out where it is during the day, but its croaking and its crawling are equally offensive during the night; and when it does come into contact, there is nothing but to submit, and let it run across, for any attempt to seize it with the hand is attended with very painful consequences, as, when alarmed, it sheds its poison more copiously than when left alone.

Nor is the very offensive danger of this loathsome reptile directed against the skin alone, for it prowls about wherever the people deposit their food, and is said to be especially fond of salt meat. It is not the quantity that it eats which is the offensive part of the matter, for its powers of mastication are but limited, but it paddles over everything, leaving the taint of its feet wherever it passes; so that, unless the people have made certain that no house gecko could pass over any provisions that may have remained in the house during the night, they have no security that those provisions shall not be poisoned; and thus, whether the fact is so or not, the uncertainty of this species of feeling is equally bad; because they who live in constant apprehension of any disease, be it what it may, always run a risk of some malady or other arising from their own apprehensions. After all, it is very probable that the ungainly appearance of this animal is the cause of no inconsiderable part of the bad name which it has gotten, because the reports of the mischief arising from it have been chiefly gleaned among a people who are equally remarkable for their ignorance and their superstition.

*A. fimbriatus*, the fringed gecko. This is a specimen of the other section of this sub-genus. It has a produced margin not only to the sides of the tail, but also along the flanks. It is an inhabitant of the island of Madagascar, and is reported to live in trees, making use of the fringed borders of its body, and the partial webs of its feet, as parachutes in leaping from branch to branch. There are several others which bear a considerable resemblance to this section in some particulars, but differ in others. One of these is the whip-tailed gecko, which inhabits some parts of the Andes, and is understood to be at least partially aquatic. It is of a black colour, and about a foot in length.

*SPHERIODACTYLI*. This sub-genus consists of a small species, which have the points of the toes formed into little palettes or discs, and the claws always retractile, but without the four-shaped plates which characterise the preceding sub-genus. In some instances the palate seems double, by being cleft in the anterior part. They are principally found in the East Indies and southern Africa.

Others, which are chiefly American species, have the palettes round and undivided. Among them we may mention the spitting banded gecko, which is a small species, prettily marked with transverse bands

of brown, divided from each other by deep red. It is found in several of the West India islands, as are also some other species or varieties about the same size, but differently coloured.

There are several other saurian reptiles which agree with the geckos in most of their characters, but differ from them in not having the toes enlarged, in having claws upon all the toes, and those claws not retractile. Of these we may just mention

*Stenodactyli*, which have the tail round, the toes striated below, and toothed on the sides. The principal species having these characters is found in Egypt. Its covering is smooth, of a grey colour, spotted with white.

*Gymnodactyli*, as the name imports, have the toes naked and slender, but the name is usually restricted to such as have the tail round, which are American species. The others, which have so peculiar a character of the tail, that they ought, strictly speaking, perhaps to form a separate genus, are

*Phyllurus*, leaf-tail. These are inhabitants of New South Wales. Their toes are not enlarged like those of the geckos, but the tail is flattened in the form of a leaf. This organ is so exceedingly brittle, that it is rare to find a specimen having it entire. One species (*P. Cuvieri*), which is found in marshy places in the neighbourhood of Port Jackson, and lives there upon aquatic insects and larvæ, is covered over with pointed tubercles. Its head is elongated, its jaws pointed, its colour on the upper part marbled with brown, and its tail in the form of a fibrous and partially twisted leaf. Another species (*P. Mili*), is smaller than the former, but longer in the legs, blunt in the head, and of a brick-dust colour on the upper part, so that it is not easily distinguished from the ground which it inhabits. The enlarged portion of the tail is near the extremity, and it has a very strange appearance, as if it were an appendage not natural, or apparently of any use to the animal, but added to render its appearance more singular.

**GEISSOMERIA** (R. Brown). An elegant flowering shrub, introduced from Brazil, belonging to *Dindynamia angiospermia*, and to the natural order *Acanthaceæ*. Generic character: calyx bracteate in five unequal parts, the back segment largest; corolla funnel-shaped, limb of two lips, the upper one two-lobed, the lower three-lobed; anthers linear and two-celled; stigma thickish; seed vessel two-celled and four-sided. These plants require a rather rich soil, in which they produce the scarlet flowers in abundance in the stove. They are propagated by cuttings.

**GENIPA** (Tournefort). A genus of South American fruit trees, belonging to the fifth class and first order of the Linnaean system, and to the natural order *Rubiaceæ*. Generic character: calyx truncate entire; corolla salver-shaped; anthers rather protruding; stigma clubbed; berry four-celled; seeds immersed in pulp. This genus is nearly allied to *gardenia*, and is treated in the same way. In their native country they yield eatable fruit, but it is not much esteemed.

**GENISTA** (Linnaeus). An extensive genus of evergreen, and deciduous, some of them creeping shrubs, and chiefly European. The flowers are monadelphous, and belong to the natural order, *Leguminosæ*. The greater number of them were known by the common English name broom, so useful to the tidy housewife, to the dyer, and to the brewer, before hops were substituted. See SEEDS.

**GENTIANA** (Linnaeus). A very numerous genus of herbaceous plants, valued for their dwarf-habit and beautiful flowers. They are pentandrous, and give a title to one of the natural orders, viz., *Gentianeæ*. They succeed pretty well in any light, rich soil, or moor earth; some of them require to be kept in pots during winter, that they may have the protection of a frame.

**GENTIANEÆ**. A natural order, containing twenty-two genera, of which there are a great many species. The gentians, which are the type of the order, are mostly dwarf herbaceous plants, with deep blue, and different shades of orange flowers. They are all pretty, and some of them extremely beautiful, though the most of them are difficult of cultivation. The *Chironias*, *Erythræas*, *Spigelias*, and *Menyanthus*, are all interesting families, and highly regarded by all lovers of plants. Some of the gentians are medicinal, containing an extremely bitter principle, of which the *Villarsias*, *Chirayitas*, and *Walteris*, partake, but in a weaker degree. The root *Spigelia Marylandica* is infused in wine as a febrifuge, and in water as a vermifuge.

Collectively considered, the *Gentianeæ* are hypocorollous *Primulaceæ*, with opposite, simple, regular flowers; stamens alternate, with the lobes, and the germen superior, and formed of two carpels. The leaves are opposite, rarely compound, sessile, or petiolate, and destitute of stipules. The outward symptoms sometimes observed to follow the administration of what has been supposed to be gentian, have proved to be owing to the *Veratrum album*, which grows in the same districts, having been collected for it in mistake. The base of the famous Portland powder is said to be gentian.

**GEODORUM** (Jacquin). An elegant flowering genus belonging to the *Orchideæ*. Generic character; sepals spreading, the lower one longest and broadest; labellum hollow and swollen, not jointed at the base; column freely jointed, apex obtuse; masses of pollen in two lobes; glands united. These curious plants are grown in pots of sandy loam and moor earth, and do better in a frame in summer than in the hot-house. They were called *Limodorum* by Roxburgh and other botanists.

**GEOLOGY**, the science which treats of the structure of our globe; its compound title being derived from two Greek words, implying a Discourse on the Earth. Some modern writers have employed the term "geognosy" as descriptive of this science; but it will be obvious that the knowledge of the earth which is here implied, can hardly be satisfactorily conceded to observers who have scarcely penetrated its crust. We prefer, therefore, the less assuming title placed at the head of this article for presenting our account of the labours of those persons who have distinguished themselves in this branch of science, referring our readers to the articles **ALLUVIAL**, **DILUVIAL**, **STRATA**, &c., for a view of the separate details, which would otherwise swell this article to an inordinate length.

It is natural that man should feel a deep interest in the history of the globe on which he is placed, and, indeed, we find that theories for illustrating the structure of the earth, and explaining the changes it has undergone during the lapse of ages, are as old, if not older, than any that are to be found for illustrating any other branch of natural history. But the geologist of the olden time, unfortunately, commenced

his labours by forming a theory, which he afterwards endeavoured to support by twisting nature to agree with his own preconceived views of the organisation of the earth—thus beginning where he should have ended. Now, however, a better directed philosophy teaches us first to investigate the laws of nature and attend to her phenomena; and then, and not till then, seek to combine the facts which actually present themselves into one intelligible whole. So that we first interrogate nature by the light of science, and then from the answers that are obtained, we conclude what must have been the probable chain of events which led to the complete formation of the vast system of wonders that we now behold.

Foreign travel, and an intimate acquaintance with every part of the globe, is commonly considered necessary for the progress of the geological student; such, however, is not the fact, as our own island will furnish all that is necessary for illustrating the fundamental parts of this science. Within a few days' journey of the metropolis may be seen vast temples reared by the hand of nature, and admirably fitted for illustrating some of her geological mysteries, which far excel all the dreams of Arabian fiction. One of these extraordinary natural structures has already been described in the article *BASALT*, where our readers will also find a description of the gigantic causeway, which is supposed at one period to have united Britain to the sister kingdom. But the geological wonders which may be thus traced rising from the bed of the ocean, are equalled, if not surpassed, by the submerged forests that are still traced with their earth-bound vestments in the very heart of our island, and where successive kingdoms of ocean and dry land have been depositing their varied produce of inhabitants for countless ages. Traces of animals and vegetables that are now the exclusive property of another hemisphere, are frequently laid bare in every part of Great Britain; and many that have left no other records of their existence, save those that the labours of the geologist have brought to light. We may take the formation of coal as an example of the extraordinary changes that have gone on in the immediate neighbourhood of the earth's surface. The black, glossy, and compact mass which we call coal, is now pretty generally admitted to be of vegetable origin. It is altogether unlike wood in its general character, and yet, from the abundance of vegetable bodies with which it is associated in some districts, and the gradual transition that is occasionally found between bodies perfectly analogous in their character, there can be but little doubt of the fact. One school of geologists supposing it to be formed by the power of heat, acting on vegetable bodies under great pressure: and another supposing it to be produced by the mere effects of time and chemical change. But we must now examine somewhat in detail the various hypotheses that have been offered by the most eminent writers for explaining and illustrating the structure of the earth.

The first theory of geology which deserves to be noticed is that of the Rev. Dr. Thomas Burnet. This celebrated author was a man of considerable genius, and his work, entitled *Tellurium Theoria Sacra*, though it cannot command the assent of the philosophic mind, will be found to display much learning and a very romantic imagination. According to Dr. Burnet, the earth was first a fluid heterogeneous mass. The heaviest parts descended and formed a

solid body. The waters took their station round this body, and all lighter fluids rose above the water. Thus, between the coat of the air and that of the water, a coat of oily matter was interposed. But as the air was then full of impurities, and contained great quantities of earthy particles, these gradually subsided and rested upon the stratum of oil, and composed a crust of earth mixed with oleaginous matter. This crust was the first habitable part of the world, and was level and uniform, without mountains, seas, or other inequalities. In this state it remained about sixteen centuries, when the heat of the sun, gradually drying the crust, produced at first superficial fissures or cracks; but, in process of time, these fissures became deeper, and increased so much that at last they entirely penetrated the crust. Immediately the whole split in pieces, and fell into the abyss of waters which it had formerly enveloped. This wonderful event, according to Dr. Burnet, was the universal deluge. These masses of indurated earthy matter, in falling into the abyss, carried along with them vast quantities of air, by the force of which they dashed against each other, accumulated, and divided in so irregular a manner, that great cavities, filled with air, were left between them. The waters gradually opened passages into these cavities, and in proportion as the cavities were filled with water, parts of the crust began to discover themselves in the most elevated places. At last the waters appeared nowhere but in those extensive valleys which contained the ocean. Thus, according to this theory, our ocean is a part of the ancient abyss, and the rest of it remains in the internal cavities, with which the sea has still a communication. Islands and rocks are the small fragments, and continents the large masses, of the antediluvian crust; and as the rupture and fall of the mass was sudden and confused, the present surface of the earth is full of corresponding confusion and irregularity.

The following passage from Burnet's work has been highly eulogised by Steele, and certainly it merits praise; it is a funeral oration over the globe: "Let us now," says he, "reflect on the transient glory of the earth; how, by the force of one element breaking loose on the rest, all the beauties of nature, each work of art, and every labour of man, are reduced to nothing; all that once seemed admirable is now obliterated; all that was great and magnificent has vanished; and another form and face of things, plain, simple, and uniform, overspreads the earth. Where are now the empires of the world? where the imperial cities, the pillars, trophies, and monuments of glory? what remains, what impressions or distinctions do you now behold? what is become of Rome, the great city; of eternal Rome, the empress of the world, whose foundations were so deep, whose palaces were so sumptuous? her hour is come; she is wiped from the face of the earth, and buried in everlasting oblivion. But not the cities only, and the works of men's hands, but the hills and mountains and rocks of the earth are melted as wax before the sun, and their place is nowhere found; all have vanished and dropped away, like the snow that rested on their summits."

The "elegant romance" of Burnet was succeeded by the work of his countryman, Mr. Woodward, who in 1695 published "*Essays towards a Natural History of the Earth, and Terrestrial Bodies*." Though he possessed a much better acquaintance with minerals

than his predecessor, and on this account had greatly the advantage of him, he produced a work far less ingenious and interesting. He also proceeded on the supposition of the Mosai history being literally true, and ascribed the present aspect of our globe to the sole influence of the general deluge. He supposed that all the substances of which the earth is composed were once in a state of solution; that this solution took place at the flood; that on the gradual retiring of the waters, the various substances held in solution, or suspended in them, subsided in distinct strata, according to their specific gravities; and that these are arranged horizontally, one over the other, like the coats of an onion. As this theory was soon found to contradict some of the plainest and most unquestionable facts which the geologists observed, it has had few admirers, and its refutation has been usually considered as obvious and easy.

In 1696, Mr. William Whiston, a man of uncommon acuteness, and of still greater learning, published a "New Theory of the Earth," from its origin to the consummation of all things. He supposed the earth, in the beginning, to be an uninhabitable comet, subject to such extremes of heat and cold as that its matter, being sometimes liquefied and sometimes frozen, was in the form of a chaos, or an abyss surrounded with utter darkness. This chaos was the atmosphere of the comet, composed of heterogeneous materials, having its centre occupied by a globular, hot, solid nucleus, of about 2000 leagues diameter. Such was the condition of the earth before the period described by Moses as the "Creation." On the first day of the creation every material of this rude mass began to be arranged according to its specific gravity. —The heavy fluids sank down, and left to the earthy, watery, and aerial substances the superior regions. Round the solid nucleus is placed the heavy fluid, which descended first, and formed the great abyss, upon which the earth floats as a cork upon the fluid metal mercury. The great abyss is formed of two concentric circles, the interior being the heavy fluid, and the superior water; upon which last the earth or solid crust we inhabit is immediately formed. So that, according to this theorist, the globe is composed of a number of coats or shells, one within the other, of different materials, and of different densities. The air, the lightest substance of all, surrounds the outer coat, and the rays of the sun, making their way through the atmosphere, produced the light which Moses tells us first obeyed the divine command. The hills and valleys are formed by the mass of which they consist, pressing with greater or less weight upon the inner coat of the earth; those parts which are heaviest sinking lowest into the subjacent fluid, and making valleys, and those which are the lightest rising higher, and forming mountains.

Such Mr. Whiston supposed to be the state of our globe before the deluge. Owing to the superior heat, at that time, of the central parts, which have been ever since cooling, the earth was more fruitful and populous anterior to that event than since. The greater vigour of the genial principle was more favourable to animal and vegetable life. But, as all the advantages of plenty and longevity which this circumstance produced were productive only of moral evil, it pleased God to testify his displeasure against sin, by bringing a flood upon a guilty world. The flood was produced, this theorist supposed, in the following manner:—A comet, descending in the plane of the

ecliptic to its perihelion, made a near approach to the earth. The approximation of so large a body raised a strong tide, and produced such a commotion in the abyss concealed under the external crust, that the latter was broken, and the waters, which had been before pent up, broke forth with great violence and were the principal means of producing the deluge. In aid of this, he had recourse to another supposition, which was, that the comet, while it passed so near the earth as to produce these effects by the force of attraction, also involved our globe in its atmosphere for a considerable time, and deposited vast quantities of vapour on its surface, which produced violent and long-continued rains: and, finally, that this vast body of water was removed by a mighty wind, which dried up a large portion, and forced the rest into the abyss from which it had been drawn, leaving only enough to form the ocean and rivers which we now behold.

In the early part of the eighteenth century the celebrated John Hutchinson formed a theory of the earth, which he professed to derive exclusively from Scripture. He supposed that when the earth was first created, the terrestrial solid matter was entirely dissolved in the aqueous, forming a tenacious chaotic mass; that the figure of this mass was spherical, and on the outside of this sphere lay a body of impure air; that within the enclosed sphere of earth or water was an immense cavity, called by Moses the deep; that this internal cavity was filled with mephitic air, similar to that on the outside; that on the creation of light the internal air received elasticity sufficient to force its way through the external covering; that immediately on this the water descended, filled up the void, and left the earth in a form similar to that which it bears at present; that when it pleased God to destroy mankind by a flood, he caused, by his own miraculous agency, such a pressure of the atmosphere on the surface of the earth, that a large portion of it was forced into the internal cavity which it had formerly occupied, and expelled the waters from it with great violence, spreading them over the surface.

Mr. Hutchinson supposed that after the divine purposes were answered by the deluge, the globe, by a process similar to that which first took place, was restored to the form which it now bears.

In 1740, the abbé Moro, an Italian philosopher, published a theory of the earth, which he chiefly derived from the works of Ray, which appeared in the preceding century. He supposed that the surface of the earth, as we now behold it, and especially the mountainous parts, arose originally from the bottom of the ocean. At first, according to him, these mountains contained neither strata of shells, nor any organised fossils; but by mean of subterranean conflagrations, earthquakes, and volcanoes, these substances were thrown up in confused heaps, after which they successively subsided according to their different specific gravities, and thereby necessarily disposed themselves in different strata. He also maintained that these submarine eruptions, while they threw up huge and irregular masses of matter, also ingulfed marine plants and animals of every kind, which subsided in like manner, and thus formed new mountains, and new beds of stones, sand, metals, and other minerals, intermingled with the remains of vegetable and animal bodies, all which remained under the sea till some new agitation threw them above its surface. He supposed that the waters by which the earth was originally overflowed, sub-

sided by degrees, the dry land appearing first in places adjacent to that where the first man was placed at the creation; that the land extended itself gradually, a considerable time elapsing before the waters had returned to their proper bed, during which time the shell-fish, multiplying in great abundance, were universally distributed by the waters of the sea; and that when the bottom of the sea was raised up by the earthquakes that accompanied the deluge, and formed the mountains, whole beds of such shells were thrown up and distributed as we now behold them.

About the year 1744, M. le Cat, a French philosopher, proposed a theory of the earth, differing from all which had preceded it. According to him, in the beginning, the substance whence metals, stones, earths, and other mineral bodies were ultimately to be formed, was a soft mass, consisting of a species of mud. The earth was a globe, or regular spheroid, and its surface was smooth, and free from hills and valleys. The sun and moon were afterwards created. The fluid which covered the mud became agitated by the flux and reflux to which it was subjected by attraction, and the mud was variously and violently moved. This agitation increasing, a part of the mud became exposed and dried. Continents were thus formed. The materials of the earth being compact and solid, the sea continually excavated its bed; and from the continual retreat of it, and the excavation of the earth, he considered this globe as doomed to be at last so perfectly undermined as to produce a confluence of the sea from hemisphere to hemisphere. Le Cat professed to believe the Sacred Scriptures, and discovered an anxious desire to show that his theory was consistent with them; but it must be obvious that it is as inconsistent with the structure and phenomena of our globe as it is with the Mosaic history.

About the year 1750, appeared the *Tellianned* of M. Maillet, a French writer of some note. He taught, that the earth was once covered water, which, by means of strong currents, raised in its bosom all those mountains which different countries bear upon their surface; that this water has been ever since continually diminishing, and will continue to diminish until it shall be quite absorbed; that our globe, being then set on fire, will become a sun, and have various planets moving in its vortex, till its igneous particles being consumed, it will be extinguished; that then it will roll through the immensity of space, without any regular motion, till it is again covered with watery particles, collected from other planets, when it will fix in the vortex of a new sun, and again go through the same course of motions and changes, being supplied with fresh inhabitants, resembling those by which it is tenanted at present; that the earth has probably been undergoing revolutions of this kind from all eternity, and will continue to go through a succession of them without end. This absurd theory, if theory it may be termed—not more hostile to revelation than to sound philosophy, seems to have gained but few adherents, and but little celebrity. But no one has proceeded to the forming of a theory of the earth with the pomp and circumstance of Buffon. It merits attention, not on account of its accordance with present appearances, or as affording plausible solutions of observed phenomena, but from the eloquence with which it is adorned, the extent of information it displays, and the popularity it derived from these sources. He supposes the planets in general to have been struck off from the sun by a

comet; that they consisted of fluid matter, and thence assumed a spherical form; and that by the union of projectile and centripetal forces, they are restrained in their present orbits. After this he supposes that the earth gradually cooled, so that the circumambient vapours were condensed upon its surface, while sulphureous, saline, and other matters penetrated its cracks and fissures, and formed veins of metallic and mineral products. The scorified, or pumice-like surface of the earth, acted on by water, produced clay, mud, and loose soils, and the atmosphere was constituted of subtile effluvia, floating above all the more ponderous materials. Then the sun, and winds, and tides, and the earth's motion, and other causes, became effective in producing new changes. The waters were much elevated in the equatorial regions, and mud, and gravel, and fragments were transported thither from the poles; hence, says Buffon, the highest mountains lie between the tropics, the lowest towards the poles; and hence the infinity of islands which stud the tropical seas. The globe's surface, once even and regular, became now rough and irregular; excavations were formed in one part, and land was elevated in another; and during a period of many ages, the fragments of the original materials, the shells of various fish, and different other exuvia, were ground up by the ocean, and produced calcareous strata, and other low-land depositions. These relics of marine animals we find at such heights above the level of the sea, as to render it more than probable that the ocean once entirely overwhelmed the earth.

Every one who contemplates the earth's surface must trace upon it marks of the most dire and unsparring revolutions, which, from the present order of things, it appears impossible should re-occur, except by the united and continuous agency of the most active powers of destruction. This, says Buffon, arose from the soft state of the former crust of the earth, and those causes, now imbecile and slow in their operation, were then more effectually exerted, and results were obtained in a few years for which centuries would now be insufficient. This amusing theorist next proceeds to contemplate the production of rivers, which he regards as having cut their own way to the ocean, as gradually wearing down the mountainous lands, filling up valleys, and choking their exits into the ocean by the transportation of finely-divided materials. Thus everything is slowly returning to its former state; the mountains will be levelled, the valleys heightened, excavations filled up, and the ocean will again cover the earth.

Buffon's theory was warmly opposed, soon after its publication, by Raspe, a geologist of Germany. He also opposed the theory of Moro, before mentioned, though he considered it as approaching much nearer the truth than the igneous fable of the French naturalist. He insisted, that the opinion of continents and mountains having been thrown up from the bottom of the sea solely by submarine conflagrations and volcanoes, was abundantly refuted by close observation. He contended, likewise, that in veins of sand, marble, chalk, and slate, there are found no indications of a burning soil, but rather of a sediment disposed by the agitation of the sea. Accordingly, he maintained, that the strata, of which the shell or surface of the earth is composed, were originally formed at the bottom of the sea by the constant agitation of the sea, and the continual production of

plants and shells; that the subterraneous explosions, and earthquakes, breaking through the bottom of the sea, not only formed banks, hills, and submarine mountains of its broken parts, but also frequently raised up such large portions of the beds of the ocean, with its incumbent strata, as to form islands or dry mountains. At certain periods, he supposed, that the presence of so large a body of water would cause it to break through the cavities made by previous eruptions, and at others, the violence of the subterraneous explosions would be so great as to remove mountains from one place to another; while the heat of the internal fires causing these explosions would be so intense as to melt, calcine, or vitrify, all adjacent substances.

In 1773, Dr. William Worthington published a theory, in which great learning and piety and a considerable share of ingenuity are combined. He maintained that the earth, in its primitive state, was plane and uniform; and that all mountains, and every thing irregular and rugged on the surface of it, are the result of the curse pronounced on the ground after the Fall of Man; that the melancholy lapse of our first parents, was immediately followed by earthquakes and every species of convulsion, which produced these dreadful effects on the surface of our earth; that the antediluvian earth greatly abounded with water, much more than at present, and that the greatest quantity of it was collected round the poles; that at first the poles of the earth were perpendicular to the plane of its orbit, and at right angles with the plane of the equator; that the centre of the earth was then the centre of gravity; that the deluge was produced by the centre of gravity being removed twenty-three degrees and a half nearer to one of the poles, which led to a corresponding deviation of the poles from their former position, and thus threw the great body of water accumulated round them on those places of the earth where little had existed before, and by these means drowned them. This event, he supposed, increased the irregularity of the earth's surface, and produced many of those phenomena, which so plainly establish the reality of a general deluge.

In 1778, Mr. Whitehurst published "An Inquiry into the Original State and Formation of the Earth." This theorist supposed, that not only our globe, but the whole of the planetary system, was once in a state of fluidity, and that the earth acquired its oblate spheroidal form by revolving round its axis in that state. In this fluid state the component parts of the earth were suspended in one general undivided mass, "without form and void." These parts were endued with a variety of principles or laws of elective attraction, though equally and universally governed by the same law of gravitation. They were heterogeneous; and by their attraction progressively formed a habitable world. As the component parts of the chaos successively separated, the sea universally prevailed over the earth; and this would have continued to be the case had it not been for the sun and the moon, which were coeval with the earth, and by their attractive influence interfered with the regular subsiding of the solid matter which was going on. As the separation of the fluids and solids increased, the latter were moved from place to place, without regularity, and hence the sea became unequally deep. These inequalities daily becoming greater, in process of time dry land was formed, and

divided the sea; islands gradually appeared, like sand-banks above the water, and at length became firm, dry, and fit for the reception of the animal and vegetable kingdoms. He supposed that mountains and continents were not primary productions of nature, but of a very distant period from the creation; that they are the effects of subterraneous fires and commotions, and were produced when the strata of the earth had acquired their greatest degrees of firmness and cohesion, and when the testaceous matter had assumed a stony hardness; and, finally, that the marine shells found in various places, on and below the surface of the earth, were for the most part generated, lived and died, in the places in which they were found; that they were not brought from distant regions, as some have supposed; and, consequently, that these beds of shells, &c., were originally the bottom of the ocean.

John Whitehurst, whose geological views we have thus briefly adverted to, was a native of Congleton, in Cheshire. He passed much of his time in Derbyshire, and investigated with considerable ability the stratification of that county. In the course of his inquiries, he has assiduously collected facts, among which his account of the mineral treasures of Derbyshire still retains much value for its accuracy and scientific truth.

Two or three years after the appearance of Mr. Whitehurst's publication, M. de Luc, of Geneva, dissatisfied with the theories which had previously been proposed, offered another, which occupied considerable attention in the scientific world. He supposed that the ocean once covered our continents; that the bottom of the old ocean was full of mountains, which neither the main waters nor any other cause known to us formed, and which he therefore calls *primordial*. These mountains rose above the surface of the waters, and formed islands. These islands and the ancient continents were fruitful and well-peopled; and the ancient sea had tides, currents, and tempests like the present ocean. These powers acting upon the soft matters which are known to have formed the bottom of the ancient ocean, produced accumulations of calcareous substances, which, in process of time, became more or less mixed with marine bodies. The rivers, in the meanwhile, carried from the land into the sea the scattered remains of animal and vegetable productions; the sea itself washed them from its coast into its bosom; and these materials, transported by currents, became a secondary soil upon its primordial bottom. Fires and elastic fluids, formed by chemical decomposition, made various openings in the bottom of the ocean, whence proceeded torrents of liquid substances and larva; which gave rise to the volcanic mountains observable on the surface of our continents. The continents which existed in a state of population and fertility, while the sea covered those which we now inhabit, though they did not form a solid mass, but were, properly speaking, vaults, which covered immense caverns, maintained their elevation above the level of the ocean by the strength of their pillars; which, being of primordial matter, were solid, and stable: but the changes which the subterranean fire produced at the bottom of the ancient sea, opened passages for its waters into the interior of the earth; the violent excitement produced by this eruption shook the pillars of the primitive earth; which, sinking into its caverns, the old continents disap-

peared, and their surface descending below the level of the waters, a general inundation ensued. This was the general deluge. The sea now covered all the globe, except the islands of its ancient bottom, which increased in number and magnitude, until the weight of the water, added to that of the superior vaults, crushed the inferior ones, and deepened more and more the new bed of the ocean; so that, at last, by a motion rapid, but not violent, all the waters retired from their former bed, and left our continents dry. Secondary mountains and other irregularities were afterwards produced by volcanic commotions, and maritime currents and convulsions.

Next to the theory of M. de Luc, appeared that of Mr. Milne, which, though it did not engage so much attention, was framed with considerable ingenuity. This gentleman declared himself a warm friend to revelation, and professed to have formed a system in strict conformity with the sacred history. In some respects he agreed with Mr. Whitehurst; in others, he adopted the opinions of M. de Luc; while, with regard to a third class of his doctrines, he claimed to be original. He supposed that the earth, immediately after the fall, and in consequence of the curse pronounced against it, underwent a total change by means of the elementary fire lodged at that time near its centre, and that hence arose the irregularities which now appear in the earth's surface. There are other geological writers who have accumulated many interesting facts, and whose insulated observations are truly curious and valuable; but their general hypotheses are of so chimerical a cast, as rather to resemble eastern allegories than European philosophy; and we are now to proceed to examine the theories promulgated by Professor Werner of Freyburgh, and Dr. Hutton of Edinburgh. Each of these distinguished writers has been ably supported by the proofs, illustrations, and comparative views, of acute and eloquent controversialists. Thus two distinguishing sects have been formed under the appellations of *Wernerians* and *Huttonians*.

The disputes and differences of these contending geologists would now be prematurely noticed. They each profess to proceed, as rigidly as the subject allows, in the path of induction; to reject mere hypothesis, and raise their theories upon accumulated facts; and yet, by a strange perversion of facts, they arrive at conclusions diametrically opposite.

The first principle of the Wernerian theory assumes that our globe was once covered with a sort of chaotic compost, holding either in solution or suspension the various rocks and strata which now present themselves as its exterior crust. From some unexplained cause, this fluid began first to deposit those bodies which it held in chemical solution, and thus a variety of crystallised or primitive rocks were formed. In these we find no organic remains, nor even any rounded pebbles; but in the strata which lie upon the crystalline, or first deposits, shells and fragments occasionally occur. These, therefore, have been termed transition strata, and it is imagined that the peopling of the ocean commenced about this period. The waters upon the earth began more rapidly to subside, and finely divided particles, chiefly resulting from the disintegration of the first formations, were its chief contents; these were deposited upon the transition rocks chiefly in horizontal layers. They abound in organic remains, and are termed by the *Wernerians* *floetz*, or secondary rocks.

It was now conceived that the exposure of the primitive, transition, and secondary rocks, to the action of wind and weather, and to the turbulent state of the remaining ocean, produced inequalities of surface, and that the waters retreated into lowlands and valleys, where a farther deposition took place, constituting clay, gravel, and other *alluvial* formations. There are also certain substances which, instead of being found in regularly alternating layers over the earth, are met with in very limited and occasional patches. Rock salt, coal, basalt, and some other bodies, are of this character, and these Werner has called *subordinate* formations. Lastly, subterranean fires have sometimes given birth to peculiar, and sometimes very limited products; and these are called *volcanic* rocks. Such is Werner's account of the production of rocks, which he arranges under the terms primitive, transition, secondary, alluvial, subordinate, and volcanic formations.

A number of delicate distinctions and accurate minutiae of description attend this theory, which we cannot notice in this brief view, and which do not affect the general conclusions. If we examine the stratification of our globe, we shall doubtless find that certain substances do occur in a certain order of arrangement, and that they appear to have been successively deposited, one upon the other, in the manner Werner would have us believe. He, therefore, and his disciples, have perhaps given a satisfactory account of their own country; but when we examine other parts of the earth's surface, so many incongruities are discovered, and so much is at variance with their leading doctrines, that we are obliged to give them up in favour of views more generally applicable.

Dr. Hutton gives a very different account of the present order of things. Looking upon the face of nature, he observes everything in a state of decay; and as she has obviously provided for the regeneration of animal and vegetable tribes, so the philosophic mind will descry, in this apparent destruction of the earth's surface, the real source of its renovation. The lofty mountains, exposed to the action of the varying temperature of the atmosphere, and the waters of the clouds, are, by slow degrees, suffering constant diminution; their fragments are dislodged; masses are rolled into the valley, or carried by the rushing torrents into rivers, and thence transported to the sea. The lower and softer rocks are undergoing similar, but more rapid, destruction. The result of all this must be the accumulation of new matter in the ocean, which will be deposited in horizontal layers. Looking at the transition rocks of Werner, he perceives that, though not strictly crystalline, they appear made up of finely-divided matter, more or less indurated, and sometimes very hard in texture, and of a vitreous fracture; and that this hardening is most perceptible when in contact with the primitive or inferior rock, which often pervades them in veins, or appears to have broken up or luxated the superincumbent masses. According, then, to Dr. Hutton, the transition and secondary rocks of Werner were deposited at the bottom of the ocean, in consequence of operations similar to those which are now active, and the primary rocks were formed beneath them by the action of subterranean fires; their crystalline texture, their hardness, their shape, and fracture, and the alterations they have produced upon their neighbours, are the proofs of the correctness of these views. It is by the action of subterraneous

fire, then, that rocks have been elevated, that strata have been hardened, and that those strata have resulted, which an examination of the earth's surface unfolds. The production of soils, and of alluvial land, is considered as dependent upon causes the same as those referred to in the other theory.

It will be observed that Hutton refers to fire as well as water for the production of our present rocks; the former consolidating, hardening, and elevating; the latter collecting and depositing the strata.

We have thus brought together a brief outline of the principal systems, or rather hypotheses, that have been employed to illustrate the history of our earth; but very considerable light has been thrown on the changes which it has undergone by those geologists who have peculiarly directed their attention to the remains of a former world that are so richly embedded in its surface. This part of the subject has, however, been fully discussed in the article FOSSIL REMAINS, to which we must refer our readers, as well as to the various articles relating to geology as they occur in their alphabetical order. To those who wish for an intimate acquaintance with all the facts bearing on this subject, we would recommend a study of the voluminous but interesting "Transactions of the Geological Society," which, added to the printed labours of Phillips, Conybeare, Ure, Buckland, Boué, Lyell, and Cuvier, contain the most extraordinary collection of facts that has yet been brought together in any branch of natural history.

GEOMETRIDÆ (Stephens). A very extensive family of lepidopterous, nocturnal, or rather semi-nocturnal, insects, known to collectors by the name of slender-bodied moth, by which term they are well distinguished from the *Bombycidae* (feathered full bodies) and *Noctuidæ* (thread-horned full bodies). From the other families of moths, *Tortricidæ*, *Teneidæ*, &c., they are distinguished by their larger size. Mr. Stephens has described more than three hundred British species belonging to this family, divided into upwards of sixty genera. The family is further characterised by the antennæ of the males being generally feathered, and those of the females simple; the palpi are mostly short and three-jointed, and the spiral tongue varies considerably in length, sometimes, indeed, being obsolete; the legs are long and slender, the posterior tibiæ being furnished with two pairs of spurs, one being placed in the centre, and the other at the extremity; the wings are of a large size, generally horizontally extended, and much variegated with markings of various colours, whence these insects are amongst the most beautiful of the *Lepidoptera*. The name of the family is derived from the Greek words *ge*, the earth, and *meter*, to measure, and is given to these insects on account of the peculiar motions of the caterpillars, which are ordinarily termed "loopers" by collectors, and which, when creeping along, somewhat resemble a pair of compasses alternately opened and shut. An example of this kind of caterpillar has been figured in the article ABRAXAS. When unemployed in walking, they stretch themselves out in a straight line, adhering to the twigs by their hind legs only, and, in many instances, so completely resembling bits of sticks, as to deceive the beholder. A figure of the caterpillar of the swallow-tail moth (*Owraptyx sambucaria*) is given in our article CATERPILLAR.

Some of these caterpillars also possess the power, when alarmed, of throwing themselves from the

leaves or twigs, having first attached thereto the end of a silken thread, by means of which they suspend themselves in the air; this thread, which proceeds from the mouth, is lengthened or shortened at will; and it is by means of this thread that the caterpillar descends from the tree to the earth to undergo its chrysalis state; it also employs the same thread to remount to its original situation when the danger is passed; this motion being effected by the insect seizing hold of the thread with its intermediate legs, between which it accumulates a greater or less mass, in proportion as it advances. Some species form for themselves slight cocoons of silk under ground, others amongst the leaves, and some are naked in the chrysalis state, and are suspended only by the tail. In their perfect state these insects offer but few particulars worthy of remark. Unlike the majority of the moths, some of these slender bodies fly during the afternoon. They abound in woods and hedges, and their flight is much lighter than that of the *Bombycidæ* or *Noctuidæ*. The males of some species present the curious character of being apparently six-winged, the lower wings being provided with a large flattened oval appendage, somewhat like a miniature wing. These form the genus *Lobophora* of Curtis. In several other of the species the females are destitute of wings, as in the *Phalæna*, *brumata*, *defoliaria*, *pedaria*, &c. The first of these species, as the name implies, is found in the winter flying, during the month of December, about the leafless whitethorn hedges, in search of its mate. In the *Règne Animal* Latreille united these insects in a single "sous-genre." Mr. Curtis has, however, divided them into two families, *Phalænidæ* and *Geometridæ*, in which the antennæ of the males are either feathered or merely ciliated, or even simple; but this step, as Mr. Stephens observes, is "evidently unnatural," since some genera have the male antennæ simple, though closely allied to insects having strongly pectinated antennæ, whilst some females have pectinated antennæ, although placed with others in which they are simple, and in which some of the males have them scarcely pectinated.

With the exception of the variations of structure and peculiarities of habit above noticed, which, of course, constitute the leading characters of the sectional and generic divisions established in this family, it must be evident that in so large an assemblage of objects possessing so many characters in common, the distinguishing marks must be of a comparatively trivial nature; hence, it will not be necessary for us, in a work of this nature, to indicate the names of the numerous generic divisions introduced into the family, and still less to describe them, and shall, therefore, only notice that the genus *Geometra*, as now restricted, comprises a beautiful group of moths, called "thorns," in which the wings are all angulated, and the male antennæ pectinated; that one of the most beautiful, although one of the commonest species is the *Abraxas grossulariata*, figured in our first volume; that another beautiful species, being the largest of the family, is the swallow-tail moth, above noticed, in which the hind wings are furnished with short tails, and that there is a very extensive and pretty group in the family, known by collectors under the name of the carpet moths, in which the wings are of a white or pale colour, with numerous undulating bands of slate-grey and other colours.

GEONOMA (Willdenow). A genus of orna-

mental palms found in South America. They have been introduced into our stove collections, and are found to grow best in sandy loam, placed in strong heat.

GEORGINA (Willdenow) is the well known DAHLIA, which see. The latter name was given by Cavanilles, but changed to the original name by Willdenow; but it does not appear to be generally adopted, as Dahlia still prevails among modern writers.

GEOTRUPIDÆ (Mac Leay). A rather extensive family of coleopterous insects, belonging to the section *Pentamera*, and sub-section *Lamellicornes*, forming part of the vast genus *Scarabæus* of Linnæus, and distinguished by the following characters:—The body is generally very convex, and orbicular or suborbicular; the thorax broader than long, and often armed, as well as the head, with horns; in the males the scutellum is distinct; the anterior tarsi fully developed; the legs inserted at equal distances apart; the jaws exposed, horny and curved; the antennæ mostly eleven-jointed.

To this family belong the genera *Bolbocerus*, *Typhæus*, *Geotrupes*, *Lethrus*, *Elephasotornus*, *Ichodæus*, *Athyreus*, and several other exotic genera. Of these the three first are British, but the third alone will claim any particular notice in a work like the present.

The typical genus, *Geotrupes* (Latreille), derives its names from two Greek words, signifying burrowing in the earth, a habit possessed by the insects in an especial manner, for which purpose their fore-legs are endowed with very great muscular power; and as they are broad and externally notched, they are well adapted for the mode of life of the insects. The body in this genus is, moreover, highly polished and rounded, so as to present but slight obstacles in the act of burrowing. The antennæ are eleven-jointed, the second joint being shorter than the third; the basal joint of the tarsi is also very short; the mandibles are exposed, and toothed at the tips; the last joint of the palpi is scarcely larger than the preceding, and the thorax is not armed with horns. The type of this genus is the well-known insect which is to be constantly observed flying about at dusk, especially in the neighbourhood of newly fallen dung, and striking against every thing which may happen to be in its way, whence we have obtained the saying, "as blind as a beetle." This insect is the *Scarabæus stercorarius* of Linnæus; it is of a shining black colour, and of an oblong oval form, but the under-surface exhibits a very splendid mixture of varying purple, green and steely blue; the elytra are deeply striated, and the stræ are ornamented with small impressed dots. The length of the insect varies from two-thirds to an entire inch.

These insects seem to prefer still dull evenings for their flight, at which time the humming noise which they make is very considerable. Probably at such periods the effluvia arising from the stercoraceous matters which they inhabit, is more widely disseminated through the atmosphere, so as to cause the insects to congregate together more numerously. They dig holes to a considerable depth in the ground under the dung, around which they have been flying, and of which they bury a portion, depositing an egg in the midst of it, which serves for the food of the larvæ when hatched. Thus do they take their share, as well as by feeding upon such matters themselves, in the general economy of nature, "not only dispersing the dung, but actually burying it at the roots of ad-

jacent plants, and, by these means, contributing considerably to the fertility of our pastures, supplying the constant waste by an annual conveyance of fresh dung, laid at the very root, by their canals; also affording a convenient passage for a portion of it, when dissolved, to be carried thither by the rain."

Our great dramatic bard has mentioned these insects more than once, and, in so doing, has proved his knowledge of the habits of the various objects of nature to have been as extensive as of the workings of the mind of man—and indeed we are happy in taking as early an opportunity as possible of vindicating our poet from those who would tell us that he always sacrificed nature to poetic effect. Such, unquestionably, was not the case, and wheresoever he speaks, not only of animals, but even of flowers, it is always with a perfect knowledge of the habits of the one, or of the time of flowering, &c., of the other. We trust soon to have the pleasure of seeing the talents of Shakspeare, in this respect, fully established by the publication of a series of essays from the pen of a distinguished naturalist, and we scarcely know any subject so capable of being made not only interesting, but highly instructive.

Macbeth, on the evening of the murder of Banquo, by murderers whom he had hired for that purpose says—

— "Ere the bat hath flown  
His cloistered flight; ere to black Hecate's summons  
The shard-borne beetle, with his drowsy hum,  
Hath rung night's yawning peal, there shall be done  
A deed of dreadful note."

Now, every one admits that the *shard-borne beetle* is the *Geotrupes stercorarius*, and not the *Melolontha vulgaris*; but commentators are not equally agreed as to the meaning of the term *shard-borne*, and as it involves the natural history of the animal, we shall not hesitate to enter into a little detail upon the subject; in fact there is scarcely a single passage in Shakspeare (except, perhaps, the "Aroint thee witch," in the same play) which has been more commented upon than the above, not only by the commentators, but also by naturalists, amongst whom we find Spence, Mac Leay, Heineker, Bennet, &c. Now, the word *shard* is rendered by some authors a broken piece of tile or earthen vessel, and so Shakspeare himself has used it in Hamlet, thus, "Shards, flints, and pebbles should be thrown on her;" and, by an easy process, the same word would be used for scales, as, where Gower speaks of a dragon "whose sharded shynen as the sonne;" and thus the scales or elytra of the beetle would be termed its shards; but Tollet, who opposes Malone, Stevens, Nares, and others, says "the sharded beetle means the beetle lodged in dung," and he cites various passages in support of such assertion; thus Bacon says "Turf and peat and cow-shards are cheap fuel and last long;" and in Dryden's *Hind and Panther*, "Such souls as shards produce, such beetle things;" and in "A true report of Capteine Probisher, his last voyage, &c. to the Orkneys," we find "They are destitute of wood, their fire is turfes and cove-shards." Moreover, Mr. Mac Leay states that *shard* is the common name for cow-dung in the north; Mr. Spence, consequently, supposes that Shakspeare originally wrote *sharn-born*. And, indeed, we find in Merrett's rare Penax, p. 201, the description of this very beetle, "*Scarabæus stercorarius* vel *fecretarius*, a dung beetle or *shard-bug*." Hence the conclusion which these authors draw is, that Shakspeare alluded not to the

scaly appendages of the beetle, but to its residence in dung, and, consequently, that we should read it the shard, or dung-born beetle, instead of the shard or elytra-borne beetle.

But Shakspeare has elsewhere spoken of these beetles with the same epithet. In *Cymbeline*, Act III., scene 3, Belarius comes out of his cave in a rock, and says—

"We house i' the rock —  
And often to our comfort shall we find  
The sharded beetle in a safer hold  
Than is the full-winged eagle."

Now, singularly enough, this passage is capable of being read with a similar double signification, both with reference to a covering by scales or elytra, and a lodging in dung; thus the interpretation given to this passage by Steevens, Malone, Holt, White, and Archdeacon Nares, is, the beetle covered by elytra is safer, as opposed to the full wings of the eagle; whilst by Tollet (who supports the interpretation of the word shard into dung), the humble earthly abode beneath dung of the beetle, is opposed to the lofty eyry of the eagle.

With all due deference, however, to these learned commentators and naturalists, we are inclined to believe that in their attempts to illustrate their author, they have laboured to show the extent of their own researches, rather than studied the passages in which these words appear, and endeavoured, by such study, to trace the application of such passages. With this object in view, let us therefore now examine the words of our author, whose wonderful knowledge of the English language was such, that he would neither make use of useless words, nor yet employ right words in wrong places.

The murder of Banquo was perpetrated previous to the evening feast. Macbeth, therefore, alludes to the period when it should take place, by speaking of the flight of the bat, and naturally connecting it with another twilight-flying animal, adds the passage in question, which we interpret, "The beetle flying with raised scales, and making a drowsy hum during its flight, tolls a natural curfew bell." If we were to adopt the other interpretation, we should find nothing to indicate the *flight* of the beetle. Whilst, on the other hand, the word *shard born*, i. e. born in dung, would be an useless surplusage.

In like manner, in the other passage we find Shakspeare's knowledge of the habits of this insect still more perfect, since, instead of regarding it, with Steevens, &c., as applying only to the safety of the beetle, in consequence of its scaly covering, as contrasted with the extended wings of the eagle, or with Tollet, as applying only to the underground abode of the beetle, we read the passage, having at the same time regard to the residence of Belarius in a cave, thus, "The beetle, with its wings folded up beneath its scales, is safer in its burrow in the ground than is the full-winged eagle." Is it possible for a finer simile to be employed? Belarius himself, a banished nobleman, living as an obscure peasant, deprived of every wordly greatness, comparing himself with the monarch who had banished him. The one leading a life of quietness in a cave, the other of constant turmoil and alarm on a throne. But there is still another passage, which we shall quote. In *Antony and Cleopatra*, Act III., scene 2, Agrippa, speaking of the love of Lepidus for Cæsar and Antony, says, "Both he loves;" to which Enobarbus adds, "They are his shards, and he their

beetle;" i. e., their love is so reciprocal that they may be said to be as much a part of the same body as are the elytra upon the back of a beetle. Any other interpretation of this passage, in favour of the employment of the word dung for shard, would be ridiculous

The shard borne beetle.

Mr. Stephens has described ten species of this genus as inhabitants of this country, but it is possible that a few of them may be varieties of the others.

**GERANIACEÆ.** This natural order is divided into two tribes, and contains five genera and above 300 hundred species. They are innocuous plants, in general slightly acid, and sometimes also astringent; hence a few have been used as astringents and vulneraries. They are also more or less fragrant, secreting resins and essential oils: in some the secretions are so abundant that, in the *Sarcocaulon L'Heretieri*, the stems burn like torches, and yield a most agreeable perfume during their combustion. The roots of *G. maculatum* are used, when boiled in milk, as a remedy for the diarrhoea in children; and at Philadelphia it is in great repute. *Erodium cicutarium* and *moschatum* are also sometimes employed as aromatic bitters, and *Pelargonium cucullatum* as an emollient; from *P. odoratissimum* a fragrant essential oil has been distilled, said to resemble the otto of rose, or at least to be as agreeable as it, and the under-ground tubercles of *P. hirsutum* are esculent, and are prized as food by the Arabs; but, notwithstanding their several domestic uses, the *Geraniaceæ* are chiefly esteemed for the beauty of their flowers, being deservedly great favourites, and some of the most fragrant and admired denizens of our greenhouses and gardens.

**GERRIS** (Latreille). A genus of hemipterous insects, belonging to the section *Geocoris*, and family *Hydrometridæ*. The body is long and narrow, the antennæ half the length of the body, and four-jointed, the rostrum four-jointed, the second pair of legs inserted at a considerable distance from the anterior pair, and very long. This genus, although introduced into the section *Geocoris*, or land-bugs, owing to the structure of the antennæ, is aquatic in its habits; from the true *Hydrocorisa*, or water-bugs (*Nepa*, &c.), its long antennæ, and the want of ciliated hairs to the legs, as well as its inability to live *under* water, sufficiently distinguish it. By every one who has had an "eye to nature" these insects must have been observed, gliding along the surface of water with great agility, by oft-repeated strokes of the long slender legs, turning in all directions, and seizing upon every smaller insect which may happen to fall in their way. The form of the body resembles that of a London wherry; and on examining more minutely the structure of the insect we shall find it admirably adapted for the per-

formance of its motions, and the consequent support of its habits. The under surface of the body is thickly covered with a fine layer of silvery hairs, which renders it impervious to the action of the water; but it is requisite that, for an insect residing upon the surface of the water, and feeding only upon such stray morsels as may happen to be floating there, that quick motion, and a power of suddenly turning in various directions, should be given to it. In the wherry we find these motions effected by long oars, acted upon from the sides of the boat and a rudder at its stern; and this is the case with the insects in question. Mr. Curtis says, "These insects, by rowing with their posterior feet, glide over the water," but this is incorrect. It is the middle legs, placed at the sides of the body in the centre, which perform the office of oars, being for this purpose much longer than the other legs, the hind pair acting at the same time conjointly as rudders. The fore legs are short, and formed for seizing the prey, which is immediately brought to the mouth.

The type of the genus is the *Cimex lacustris* of Linnæus. The several British species, but their characters are not sufficiently elucidated, since we are convinced that the supposed apterous species upon certain occasions acquire wings, as is the case with the other genera of the family.

GERVILIA (DeFrance). This genus contains several species of fossil shells, found in the department of La Manche: the animal and, of course, all recent species are altogether unknown: it is classed immediately preceding the genus *AVICULA*, which see for its classification.

GESNERIA (Linnæus). Under-shrubs and tuberous-rooted herbs, mostly natives of the West Indies; class and order *Didymia Angiospermia* and natural order *Gesneriaceæ*. Generic character; calyx attached to the germen, five-cleft; corolla tubular, full at the upper part, limb nearly equally divided, often two-lipped, spreading or reflexed, upper lip two, lower one three-lobed; stamens have ovate, two-celled anthers; style with a two-lobed stigma; capsule of one cell, containing minute chaffy seeds. These plants require a light rich soil, and may be propagated by cuttings.

GESNERIEÆ. A small natural order of tropical herbs with large downy leaves, and bearing purple or scarlet flowers. The inflorescence is spicate, branching or paniculate, seldom solitary; the flowers irregular; the calyx is free, half adhering or joined to the germen; the corolla is perigynous or hypogynous, irregularly five-lobed, somewhat two-lipped, the upper one two-lobed, the lower one three-lobed; the disc is annular, perigynous and studded with glands; the stamens, four in number and didynamous, inserted in the tube of the corolla; filaments free; anthers two-celled; the germen is formed of two connate carpels, containing many seeds; style one, bearing a headed stigma. The *Gesneriaceæ* are very ornamental plants, but their economical value is little; some have been used as dyes, and the fleshy fruits of others are eatable: they are sweetish and mucilaginous, but not much prized.

GEUM (Linnæus). A genus of hardy herbaceous perennials, chiefly natives of the northern parts of the world: two of them are common British plants, where they are called *Avens*. They belong to the natural order *Rosacææ*: a species of saxifrage is also called *geum*.

GIANT FENNEL, is the *Ferula communis* of Linnæus; one of genus of large herbaceous plants belonging to *Umbelliferae*.

GILLIESIEÆ. A natural order, allied to the *Asphodeleæ*, but separated by Dr. Lindley. The order contains only one or two genera, viz., *Gilliesia*, and *Mersia*, both Chilian plants, with small inconspicuous, irregular liliaceous flowers, grass-like leaves, and tunicated bulbs, by which they differ from the *Asphodeleæ*. They are neither ornamental nor useful, although, from their structure, curiously interesting plants.

GILLYFLOWER, is the *Mathiola incana* of R. Brown. This, under the name of stock-gillyflower, is one of the oldest favourites of the florist. Under cultivation the flowers become double, and vary into many different colours: they are at the same time delightfully fragrant. Some of the species are annuals, and others biennial. They belong to the natural order *Cruciferae*.

GINGER, is the *Zingiber officinale* of Roscoe. A plant which yields a useful spice and condiment. The tuberous root is the useful part, obtained by cultivating it in fields on a large scale in the East Indies, and forms, at present, an important article of commerce from both Indies. It belongs to *Scitamineæ*.

GINSENG, is the *Panax quinquefolia* of Linnæus. As a drug, it has been from time immemorial extolled in China as a universal panacea or remedy for all ills. Pere Jartroux says that the most celebrated physicians of China have written volumes on the *Gin-seng*, which they affirm to be able to ward off or remove fatigue, to invigorate the enfeebled frame, to restore the exhausted animal powers, to make old people young, and, in a word, to render man immortal—"if any thing on earth can do so." Hence the name *Gin-seng* signifies, "the dose for immortality." Osbeck says the Chinese take it every night and morning in their tea or soup, and that he never looked into apothecaries' shops but they were always selling *gin-seng*. The plant is a native of North America, as well as of Chinese Tartary; it grows chiefly in desert places, difficult of access, or at least the venders tell strange tales of dangers encountered by those who collect the root, perhaps with the design of enhancing its value; and it has been known to cost its weight in gold.

GIRAFFE (*Camelopardalis*). A very singular genus of ruminating mammalia, one of the most singular indeed of the whole class, and an inhabitant of very peculiar pastures. The history of this animal, in different ages of the world, is as checkered as its appearance is peculiar. That it was known to the ancient Romans, and brought among other African animals to Rome, there is little doubt; and it was from the Romans that it received the generic name which it still retains, though in common language it is now known by the less exceptionable one of giraffe. Camelopard is of course compounded of the two words camel and panther, with neither of which this animal has a very close analogy. It no doubt belongs to the same order with the camel, is found in the same parts of the world, and feeds on substances not very different; but its general aspect is very different from that of the camel, and to those who have seen the more common animal and not this one, the association of the idea of a camel with the name would give a very erroneous impression. It is worse with

the other part of the name, pard, which means leopard or panther, or in fact any of the larger spotted animals of the cat tribe, with which the giraffe has nothing in common, farther than it is also a spotted animal.

The first account which we have of the giraffe being publicly exhibited to the Romans, was by Cæsar at the Circensian games; but from the representations of it that remain in ancient mosaics, especially in the Prænestine pavement, in which it is represented both browsing the branches over it and in grazing the more humble vegetation under, there is reason to believe that it had not been rare in the subsequent period of Roman history. The Romans obtained their wild animals for exhibition chiefly from northern Africa, where no giraffes are now to be found; and this would lead us to conclude that northern Africa has undergone considerable changes since that period, and that, as the desert has encroached upon what was formerly the most fertile possession of man in Egypt, so it has, in like manner, encroached on the pastures of wild animals all round, until many of those which were common over great part of the African continent at one period of history, are now confined within comparatively narrow bounds.

The giraffe is mentioned by several ancient writers, but the earliest correct account of it which has come down to us, is that given by Heliodorus the Greek bishop of Sicea, in his *Æthiopica*: "The ambassadors of the Axœomitæ (the Abyssinians)," says the bishop, "brought presents to Hydaspes, and, among other things, there was an animal of a strange and wonderful species, about the size of a camel, which had its skin marked with florid spots; the hinder parts from the loins were low, like those of the lion, but the shoulders, fore-feet, and breast, were elevated above proportion to the other parts; the neck was small, and lengthened out from its large body like that of a swan; the head in form resembled a camel's, but was in size about twice that of a Lybian ostrich, and it rolled its eyes, which had a film over them, very frightfully. It differed in gait from every other land or water animal, and waddled in a remarkable manner; each leg did not move alternately, but those on the right side moved together, independently of the other, and those on the left in the same manner, so that each side was alternately elevated. This animal was so tractable as to be led by a small string fastened to the head, and the keeper could conduct it wherever he pleased, as if with the strongest chain. When it appeared it struck the whole multitude with terror, and it took its name from the principal parts of its body, being called by the people, extempore, *camelopardalis*."

The word giraffe, which has been adopted as the modern name, is understood to be African, though it is said to be derived from an Arabian corruption of the original term. It is of little consequence, however, by what name this animal may be called; for there is no danger of confounding either its appearance or its characters with those of any other known animals.

It stands alone; and though it is decidedly a ruminating animal, and one of the most gentle of the whole order, though timid and exceedingly difficult to capture when in the wild state, it has little in common with any other. The length of the neck, the callous appendages on the knees and the sternum, give it some resemblance to the camel; and the head also has some slight analogy to the head of that ani-

mal; but here the resemblance ends. The body, which is very handsome, is peculiar in its form; and the legs, though they exceed in length those of every known animal, partake of the joint characters of those of the horse and the antelope; while the tail is not unlike that of the ox tribe. The feet agree with those of the horse, in being without the spurious hoofs which mark most of the ruminant animals, and in the peculiar enlargement of the base; but the hoofs are divided, and thus the foot altogether is different from that of the horse, and also of the camel, which has the foot of a very different texture, and is not adapted for the same fleet motion as this animal. Some idea of the form of the animal, and its altitude while browsing the young branches of its favourite acacia, and which it seizes by its prehensile tongue, may be obtained by inspecting the plate GIRAFFE, where the animal is very faithfully and forcibly represented in two attitudes, and the artist has succeeded in delineating the mild expression of the animal as well as the form.

Many attempts have been made to trace resemblances, or, as they are called, affinities, between the giraffe and various other ruminating animals; but it does not appear that any of them have been tolerably successful, for while the likeness has been apparently made out in one part, there has always been so palpable a contradiction in some other part, as to render the whole of very little value. The characters of the genus, or rather of the group, or sub-order,—for though there is but one known species, and we have no evidence that there ever was more than this one, it requires this distinction,—are the head in both sexes furnished with a species of horns, which consist of prominences of the frontal bone, which rise parallel to each other to the height of about six inches in the male, but rather less in the female. They contain no true horn in their substance, but are merely a cellular enlargement of the bone, of nearly equal thickness throughout the whole length, and with the upper extremity formed like a sort of cushion, and beset with a sort of bristly hairs. Those appendages to the head are of course never shed, they are not at any time bare of skin, nor does the animal use them for any known purpose either of defence or in its more peaceable economy. These curious horns, or rather appendages, for they contain no horn in substance, unless the stiff hairs on their extremities are to be considered as such, are not absolutely continuations of the frontal bones, for in the young animal they are united by a distinct suture; and there is a third tubercle of bone, much broader but not near so high as the others, articulated on the middle of the frontal, intermediate between them. The only known species is,

THE GIRAFFE (*Camelopardalis girafa*). This, when full grown, is by much the tallest of animals if measured from the hoofs of the fore feet to the top of the head. From fifteen to eighteen feet is mentioned as being the height of the majority, though specimens have been seen as high as twenty feet. A considerable portion of this height arises from the length of the neck, though the shoulder is also high, much higher in proportion than the rump. Some have said that much of the apparent height of this part of the body is owing to the great length of the spinous processes of the scapular vertebræ; but though these processes upon the anterior part of the spine are long, and thus afford firm points of insertion to the muscles of the shoulder, yet the great height is in

the legs and the neck, which answer to each other. Behind the animal is not so high, and in that part it appears lower than it really is, as the hind legs are partially bent when the animal is browsing at the full stretch of its neck. On the other hand, when it feeds on the ground, which it can do much more easily than is generally supposed, it has to diminish the height forwards by setting the fore feet apart from each other, as is done by the young of the horse in their first attempts to graze.

Altogether the appearance of these animals, though peculiar, is very graceful. The body is short, compact, and well filled up and rounded. The limbs are clean, but at the same time strong and muscular, and the form of the neck and its union with the head are very symmetrical. The head is light and airy in appearance, and has not the least appearance of being a burden on the neck, as is the case with some other ruminants. The ears, which are long and have a good deal of motion, are handsomely formed. The eyes are large and clear; and it is placed in a peculiar manner, occupying so prominent a place on the sides of the head that they command perhaps more of the horizon than those of any other animal. In this respect they bear some resemblance to the eyes of the hare; and they appear to answer a purpose something similar—that of watching against danger from behind, which is the chief danger to which this fleet and strong but inoffensive and gentle animal is exposed.

The colours of the giraffe are disposed in a very pleasing manner. The ground colour is whitish, but with a tinge of warm cream colour, and the spots, which are brown and nearly square in shape, give it the appearance of being cross-barred with the paler colour. When young the sexes resemble each other in their colours; but as they advance, the spots on the male become of a dark brown, while those on the female retain more of their original rust-coloured tint. Both are, however, subject to some varieties of colour, perhaps in proportion as they are differently exposed to the action of the sun.

The hair on the body is short, and lies flat and smooth on the skin; but the neck and upper part of the back are furnished with a short mane. At each side of the commencement of this mane on the occiput, there is a bony tubercle on the skull, which tubercles appear as the rudiments of a second pair of horns; so that if we include the flat one in front, there are bases for five horns on the head of the giraffe, though there is not a true horn on any of them. The tail is strong, reaching beyond the heels, sort haired for the greater part of its length, but furnished with a handsome brush of strong hairs at the tip. The true hoofs are firm and strong, and of a black colour, and, as we have already observed, there are no false hoofs. Though the animal is by no means rare in its native localities, it is so shy in a state of nature, and so well formed for getting speedily out of sight, that its economy is but little understood. The common report is, however, that the female goes twelve months, and never has more than one at a birth.

Giraffes, at least as well ascertained, are confined to Africa, though some of the authorities mention them as also occurring in Asia, but in what particular place of Asia is not stated; it is not impossible, however, that they may exist in some unexplored parts of the warm regions of that quarter of the world,

which resemble in climate, seasons, and productions, their African haunts. The pertinacity with which it was long maintained that no lion existed in any part of India, and the discovery of several of these animals after the country became a little better explored, should teach us to pause before we positively decide what tropical production, whether animal or vegetable, does not exist in so extensive and so varied a country as India.

At present, however, we know the giraffe only as an African animal; and there chiefly as an animal of the southern parts, at least to the countries to the southward of the desert. It is not found on the coast of Guinea, where there are more frequent rains and greater fertility but a less healthy climate, than far into the interior, and nearer the Great Desert; nor does it appear that the giraffe is any where found on low and marshy grounds. Indeed the form of its feet, and its structure taken altogether, are ill adapted for such places; and any one who examines even a tolerably well executed figure would at once decide that the giraffe inhabits dry pastures, and breeds upon firm ground. Its numbers in central Africa, south of the desert and south-west of Abyssinia, have not been very clearly ascertained; but it certainly does range in latitudes from about that parallel southward to the confines of the Cape Territory, where it is not unfrequently met with in the woods near Orange River. The natives, especially the wild bushmen, hunt it with considerable avidity. The flesh of the young ones is described as being both tender and of good flavour; and though the old ones may, from the vigour of their muscles, and the heavy exercise which these undergo, be a little tougher, we may naturally enough suppose that they would be acceptable to a people who do not hesitate to make a meal of the lion himself. The most valuable parts are, however understood to be the skin, as an article of domestic economy, and the marrow of the long bones as a luxury in the way of eating. The skin is described as being very tough, hard, and durable; and to those who like luxuries in the way of fat, the marrow is said to be a *bonne bouche*. It is generally in the way of curiosities, however, that the skins of these animals find their way, by the Cape of Good Hope, to Europe; and it was not till a comparatively recent period that these were common even in museums; and they were generally so mutilated that it was not easy to make out the characters of the animal from them. An opportunity was afforded some time ago to the curious in this country of correcting any mistakes that may have been made in this way, by the arrival of a living specimen, as a present to his late Majesty George IV. This one lived for some time in this country; but either the climate, the food, or both, did not agree with it, and it died. Its remains have, however, been preserved; for being presented to the Zoological Society of London, that society had the skin stuffed, and the skeleton set up in its proper arrangement and attitude; so that any one who chooses to visit the Society's Museum in Bruton Street may have an opportunity of studying a giraffe "skin and bone," if not in flesh and blood and its living economy.

In their native country those animals show their peaceable disposition in being partially gregarious. They are found in small flocks of about five or six; and from what has been said of the period of gestation, and the single young one at a birth, these cannot

Giraffe.

be considered as families, or any other associations than those arising from simple attachment of the species to each other, upon the common principle of sociality among gregarious animals. This circumstance, together with the mildness of these majestic creatures, renders it highly probable that they might be domesticated by proper treatment; and though the best use to which a giraffe could be turned is rather an indeterminate problem in domestic economy, there is no question as to the great ornament which these animals would afford, if it were possible to breed them, or even to keep them, in collections of ornamental animals. It is probable, however, that before this could be done, they would have to pass through successive gradations of climate, and that even then the experiment might prove a failure.

Giraffes do not appear to live in the very close forests, near the river banks, where the giant vegetation of Africa has its growth. Their locality is rather in those places which may be considered as holding a mean proportion between the excess of tropical vegetation and the final sterility of the plantless wilderness. Those confines of the forests which are on the margins of the deserts and karoos, seem to be their chief localities. Those places are generally scattered over with trees, chiefly acacias, which do not form a perfect brush of underwood at the bottom, as is the case with the shrubs nearer the desert or the plain, and which brushy woodlands answer better for sheltering a lion or other powerful beast of prey, than the acacias in question. Still these acacias do not grow to any considerable height; and the young branches are pendent and succulent, and it is upon them that the giraffes subsist, at least for a considerable portion of the year,—for that portion when the ground under them is destitute of verdure and hardened like a brick.

Under ordinary circumstances, the giraffes browse their favourite acacias in peace and safety. It is true that the poisoned arrow of the Bushman sometimes finds them in these places, by his stealing upon them from tree to tree, till he gets within range; but probably this happens less frequently than in the case of any other African game. The eyes of the giraffe are, as we have said, admirably placed for keeping watch against danger from behind; and the stem of the tree which the animal is browsing, forms no bad defence to it in front. Then, if it is once alarmed, and trots or ambles off at its peculiar pace, which though, as mentioned by the old bishop of Sicca, it has a shambling appearance, is yet very swift, and it is one of those species of motion which an animal can continue for a long time. And if the giraffe is once alarmed and takes to flight, it is not very safe any more than very easy, to attempt coming up with him; but the reason of this we can notice to more advantage by and bye.

The lion appears to be the only wild animal of which the giraffe needs to have any fear; and as the lion attacks only from an ambuscade, like the Bushman, the same defence, or watchful protection, which guards against the one, serves also to guard against the other. The lion does not in general prey at those hours when the giraffe is feeding; and if he did, he could not spring upon the giraffe in any way but from behind, as there is the protection of the tree in front. It is said also, that even the claws of the lion, unless when he can get upon the ridge of the animal, and hold on upon both sides do not penetrate

so far into the very hard skin of the giraffe, as to prevent that animal from shaking him off; and if it should succeed in this, the fate of the lion is as certainly sealed as when the elephant stamps, kneels, or otherwise crushes him to death, though it is sealed in a manner somewhat different. The defence of the giraffe is kicking; and from the vigour of its muscles, the length of its legs, and the consequent velocity of the hoof, when it comes to the position in which it can take effect, the kick is a truly formidable one, and it can be repeated with great celerity. The full effect of one kick is said to be sufficient to break the skull of a lion, strong as it is, and this is by no means unlikely, for the stroke of the kangaroo, which is a much lighter animal, can break the skull of a dog. The eye of the giraffe also sees to the rear, and can guide this its formidable weapon, both as to the time and the direction of the stroke; so that there is danger to anything that may come within its reach. Even if the first kick should not be fatal, another can be made to follow so soon, that the stunned foe is killed or crippled before he can recover himself. The animal does not appear, however, to put this powerful weapon to the proof, except in cases of necessity; for its first attempt at safety is flight, and that is in most cases sufficient.

The times at which the lion is said to attack these animals with the greatest chance of success is, when they seek the water-courses for the purpose of drinking. This is usually in the morning; and the lion lies in wait at some place more elevated than that of his intended prey. When it reaches down for the purpose of drinking, all the advantage which its eye gives it when the neck is elevated is gone; and from the position of the fore-legs during this operation, it could not kick with the same force which it does when on the level ground, and in full command of itself. In this situation, the lion sometimes succeeds in fastening upon its back; and though the animal bounds off with great speed, the weight of the lion, and the pain of the laceration, which he inflicts both by claws and teeth, ultimately bring it to the ground, and when once there it is altogether helpless. Sometimes, too, when the giraffe, finding its food become scanty in those more open places which it frequents at other times, seeks the beds of the streams for such trees as may still remain there in a state sufficiently succulent for its subsistence, the lion, who has been crouching in a bush upon some commanding point, will sometimes spring to the attack, and chiefly from his elevation above the giraffe, succeeds in making it his prey. In general, however, we believe we may repeat that, with the exception of the elephant, which the lion seldom attacks, and of the rhinoceros, and the hippopotamus, which set him at complete defiance, or rather are perfectly indifferent to him in the peculiarity of their habitations, and the strong mail of their skins, the giraffe is less preyed upon than any other animal.

The giraffe, however, has its head quarters in a country which is very little known to modern travellers; as it has at most been visited only on the confines. Its principal country appears to lie nearly in the direction of the meridian, about twenty degrees east longitude from Greenwich; and it is rarely found near the coast along the whole extent. Although therefore the animal itself is now well known, its manners in those wild forests are to a great extent matters of mere guess-work, upon which it would be

equally unnecessary and unwise to enlarge. It seems, however, to be peculiarly fitted for making rapid way over rough and stony grounds, where scarcely any other animal could keep its feet even at the slowest pace; and its peculiar mode of ambling, in which it lifts two feet at each side alternately, and bounds along, almost as if it were a sort of biped, fits it remarkably well for clearing the large stones which encumber the surface of a country, so alternately burnt up by drought and scourged by heavy rains as that through which it has to pass.

We omitted to mention, when speaking of the characters of this singular animal, that it has neither a muzzle nor lachrymal sinuses; that it has twelve grinders and eight cutting teeth in the lower jaw, and twelve grinders without any cutting teeth in the upper; and that the female has four mammae, which are situated in the groin.

**GLADIOLUS** (Linnæus). A genus of tuberous plants, and one of the finest ornaments of the flower-garden. The flowers are triandrous, and belong to the natural order, *Iridæ*. Generic character: spatha two-valved, grassy; corolla six-parted and rather gaping; stamens rising upward, bearing anthers attached to the filaments by their back, at a point a little above the base; stigma trifid, recurved; capsula oblong, three-sided; seeds winged. The Asiatic and European species have been long in our gardens, and known by the names of the sword-lily, or corn-flag; but a vast accession of species have been received from the Cape of Good Hope, some of which are most elegant plants. The European sorts do very well in the open borders; but the Cape species require to be treated like other bulbs from the same country, that is, potted in sandy leaf-mould, kept dry when dormant, fresh potted in October, and afterwards placed in a frame and regularly watered after they begin to grow.

**GLAPHYRIDÆ** (MacLeay; ANTHOBII, Latreille). A sub-family of coleopterous insects, belonging to the section *Pentamera*, sub-section *Lamellicornes*, and family *Scarabæidæ*, belonging to the group which feed upon the juices of trees or flowers (*Thalero-phaga*), having the mandibles horny, concealed by the clypeus, the upper lip advanced, and the lobes of the maxillæ membranous. These insects appear to be confined to the old world, frequenting flowers, principally the vernal species, preferring that of the *Liliaceæ*; and, from the hairiness of their bodies, they must be very serviceable in promoting the fecundation of plants.

The genera are: *Glaphyrus*, *Amphicoma*, *Anthipna*, *Chasmodontus*, *Chasme*, *Dichela*, *Lepitrix*, *Pachygenemus*, *Anisonyx*, and some others; the majority comprising insects of small size, but considerably variegated in their colours.

**GLAREOLA** (*Pratincole*). A very peculiar genus of birds, ranged by Cuvier in his order *Echassiers*, or stilt birds, and forming one of those three small families which stand in a great measure apart from the rest. Those doubtfully classed birds are the carrion bird of New Holland, the flamingo, and the genus under consideration, none of which agrees in all respects with the proper stilt birds; and two of them, the carrion bird and this genus, are not stilt birds at all, for they have very short legs; and it does not appear that they are in any way fitted for wading, or given to such a practice, though all the three families frequent the margins of the waters.

The characters of the present genus are, the bill short, conical, arched in its whole length, with the gape wide, and in its general form bearing a very considerable resemblance to the bills of the gallinidæ, with which, however, the birds have little in common; and they have even less resemblance to partridges, although they have, strangely enough, been called sea partridges, both in Britain and in other countries. Their wings are very long and pointed, longer, indeed, than the wings of any known species. In some of the species, too, the tail is very much forked; and the whole apparatus of flight in the birds bears a considerable resemblance to that of the swallow tribe, with whom, also, they have been confounded by some naturalists, though they do not appear to have any natural affinity to these birds. Their flight, indeed, is something after the style of the swallows, or rather of the terns, but they differ from these in not having the feet webbed, except for a small space between the outer and inner toe. Their legs are of medium length, with scutcheoned scales on the tarsi; and not reticulated ones, as in the true wading birds. They have three toes to the front, and one to the rear, the latter of which touches the ground when they walk. They frequent the margins of the water, along which they usually fly in flocks, and utter loud and piercing cries; their food is understood to consist chiefly of worms and aquatic insects, the last of which they capture on the wing, beating the surface of the water for them something in the manner of swallows.

These birds are remarkable for the closeness and compactness of their plumage, upon which there scarcely appears a loose feather to retard their flight, even in the under covering of their wings. Indeed, their covering is altogether so compact, that it is not easy to discover in it much difference between feather and feather. Their colours are not gaudy; but they are in general rather rich, and well contrasted, so that on the whole they are very handsome birds.

They appear to be chiefly confined to the eastern continent, to the east part of Europe, and to central and southern Asia; but some of them are also met with in the south-eastern isles. Their power of flight is indeed such, that a few hundred miles, more or less, does not appear to make any material difference in the ease of their journeys. The species which is best known in eastern Europe, if, indeed, it is not the only species which is found there, does not come to the British shores, or even beyond the valley of the Danube, and not, as it should seem, even near to the head of that valley as a regular visitant. But still one will sometimes make a dash across; and as they have no western locality, there is no doubt that they come from those eastern countries which we have mentioned; and when they do come into Britain, they do not, as is the case with most of those eastern strays, alight on the east coasts of the country, or in latitudes corresponding to those which they inhabit when in their proper home. If one crosses the north sea, the chance is that it will not alight until it is on the most westerly of the Hebrides, or the northmost in the Shetland islands; and there, when one does come, which, however, is but rarely, it appears to be quite at home with the gulls and terns, which are abundant in these remote places. Such as come there show few signs of fear, and thus they become an easy prey to collectors of birds, by whom they are much prized on account of their rarity. There are several species, though some of them are not very clearly made out,

*G. torquata* (Collared Pratincole). The length of this species is about nine inches and a half; the plumage is subject to considerable varieties of colour. It inhabits the banks of large rivers, inland seas, and lakes, in the provinces which confine on Asia, and in most of the southern countries of that continent; is very common on the salt lakes and extensive marshes of Hungary; and is a stated or accidental passenger in some parts of Italy, Germany, France, and Switzerland, but is scarcely ever met with in Holland and Great Britain. One, we believe, was shot near Liverpool, and another specimen was shot in Unst, the most northerly of the Shetland islands, by Mr. Bullock. This bird darts with wonderful rapidity on flies and other insects that live among the reeds and rushes, and seizes them whilst it either flies or runs. It is a noisy restless bird; and the female seeks out the tallest tufts of herbage for her nest, where she lays from three to eight eggs.

Though this bird is subject to very considerable varieties of colour, some of which appear to be permanent, and yet attended with no other difference of character or of habits, yet the following may perhaps be considered as the prevailing colours of the full-grown birds of both sexes, which do not indeed appear to differ much from each other. The top of the head, the nape of the back, the scapulars, and the wing-coverts, of a greyish brown colour. The throat and fore part of the neck white, with a light rose-coloured tint, and this portion is surrounded by a very straight and well-defined band of black, which returns toward the angles of the gape; and it is from this that the bird gets the name of collared. The space between the eye and the bill is black, but there is a small crescent-shaped spot of white behind the eye. The breast is brownish white, the under coverts of the wings bright maroon red. The under part of the body white clouded with russet; the under tail-coverts pure white; the tail-feathers black, but with brownish orange margins, and the quills of the wings margined with the same colour, and deep blackish brown in the centre. The bill black at the tip and reddish at the base; the irides reddish brown; the feet reddish ash; and the circle round the eyes bright red. There is a variety of a greyish brown, deeper or paler in the tint, with the white on the throat clouded with bright russet; and this variety sometimes has the black collar broad, sometimes marked by a white line, and sometimes consisting of a row of spots. The young birds are brownish ash on the upper part, waved with darker, and with whitish margins to the feathers; the throat dull black; and the breast and belly dark grey, with brown spots. In this state of the plumage they have often been described as different species.

*G. grallaria* (Australian pratincole). The upper parts of this species are reddish fawn-colour; the quills black; the breast russet; the throat, fore part of the neck, rump, and tail-coverts white; the belly and flanks maroon brown. The anterior part sometimes marked with blackish spots, forming a sort of collar. The tail-feathers squared over at the end; the first quill very long and narrow; the bill reddish, and black at the tip, and the feet reddish; the length about nine inches; and the closed wings reaching nearly three inches beyond the point of the tail.

*G. lactea* (cream-coloured pratincole). All the upper parts of the body and the wings pure whitish ash; the quills and under sides of the wings deep black; all the under parts of the body pure white; all the

tail-feathers, with the exception of the outer ones, have a black spot upon each, which forms a large angular space on the closed tail. The bill is black with reddish margins, and the feet brown. The length of this species is much less than the others, it being not quite six inches. It is understood to inhabit India.

There are several other species of those birds mentioned by describers, as being distinct from those which have been enumerated; but when the differences consist in the colours or the markings only, they may be disregarded, from what we know of the proneness to variety of colour in that species with which we are best acquainted. The peculiar form and comparative shortness of the tail in the Australian one, leave little doubt that it is entitled to rank as a distinct species; and which differs from the others not only in size but in the peculiar form of its tail, which is much less produced and forked than in the collared species, but much more so than in the Australian one. These birds are a very peculiar race, but their motions are so rapid, and the marshy places which they inhabit are generally so inaccessible, that our knowledge of them is very limited.

GLAUCUS (Forster). A naked mollusc found in nearly every sea, but which has, hitherto, been erroneously figured and described with the foot uppermost.

GLÉCHOMA (Linnaeus). A genus of two creeping perennial herbs, natives of Europe, and well known by the name of ground-ivy. The *G. hederacea* was once much esteemed as a medicine, and administered in pectoral diseases. Ground-ivy tea is still taken as an article of diet by poor people, and occasionally as a medicine; and cases are on record in which it has been useful for hypochondriacal patients. It belongs to *Labiatae*.

GLEDITSCHIA (Linnaeus). A genus of hardy deciduous trees, natives of North America and China. Class and order *Polygamia Diœcia*, and natural order *Leguminosæ*. Generic character: flowers bisexual; calyx three to five-parted; petals from three to five, two sometimes united; stamens from three to eight; filaments filiform, free below; anthers erect, oval, two-celled; style simple, short; pod often very long, interrupted by contractions between the seeds, the latter merged in pulp, rarely one-seeded; the male flowers have a calyx in four or eight parts; corolla none; stamens four to eight. These trees are admitted into arboreetums and ornamental plantations. They have the habit of the *Acacia* (Robinia), and some of them are remarkable for their large branched thorns, by which their boles are effectually defended from all climbing animals. Not even a bear could ascend the *G. horrida* with impunity.

GLOBBA (Roscoe). A genus of fine plants, belonging to the first class and order of Linnaeus, and in the natural order *Scitamineæ* of Jussieu. Generic character: calyx somewhat tubular and three-cleft; corolla double, the exterior three-parted, the interior one-lipped, with two teeth at the base; stamens with linear filaments, not produced beyond the anthers; style filiform, bearing a concave stigma; capsule associated. These plants are easily cultivated in the stove, grown in sand and peat earth. In India and China they affect the sides of ponds, and there grow luxuriantly.

GLOBE THISTLE, is the *Echinops sphærocephalus* of Linnaeus. Like all other thistles, it belongs

to the natural order *Compositæ*, and is found wild in the central countries of Europe.

**GLOBULARIA** (Linnæus). A genus of herbs and undershrubs, natives of the south of Europe. Linnæan class and order, *Tetrandria Monogynia*, and to the natural order to which it gives a title, *Globulariæ*. Generic character: flowers aggregated in round heads; receptacle chaffy; involucre imbricated; calyx in five persisting divisions; corolla in five irregular divisions; stigma simple; caryopsis loosely involved in the calyx; embryo inverted. The globularias are pretty flower-border plants, affect a sandy soil, and may be propagated by cuttings or seeds.

**GLOBULARIÆ**. A natural order, containing only one genus, whence it derives its title. The species are Alpine plants, bearing pretty blue flowers; some of them are purgative, and, as such, are found in the list of drugs. The *Globulariæ* differ so little from the *Dipsacæ* in their general structure, that, were it not for their free superior germs, they might be associated immediately with them, at least they might very well stand as a sub-type, for they are an instance of the close connexion which exists between these types, and thus become another evident link in that beautiful chain of affinities which pervades the whole vegetable kingdom, associating and assimilating the most distant, and apparently the most discordant parts.

**GLORIOSA** (Linnæus). A genus of bulbous or tuberous-rooted plants, natives of India. Class and order, *Hexandria Monogynia*, and natural order *Tulipacææ*. Generic character: corolla of six petals, reflexed from the base, petals lanceolate, pointed, wavy, and very long; stamens below the germen; filaments awl-shaped, elongated, spreading; anthers incumbent; style like a thread, inclining; stigma trifid; seed-vessel three-celled, three-valved; seeds globular, and disposed in a double series. The botanist who first discovered this plant must have been enchanted by the sight, because he bestowed upon it the high-sounding name of *Gloriosa superba*. It is really, however, a magnificent plant even in our hothouses, and in its native bed must be indeed glorious. They are flowered frequently in our hothouses with the necessary culture of planting them in turfy loam, sand, and moor earth, placing them in a hotbed-frame till they begin to produce their long dangling stems; then remove them to a warm part of a stove where there is room for the stems to advance, and be trained on a wall or to a long stake. They flower in the summer, and the stem dies down in the autumn, after which it is necessary that the roots should be kept perfectly dry till the next spring. They are then re-potted, and plunged in a brisk heat of the bark-bed, and at all times moderately supplied with water. They are increased by division or by seeds.

**GLOSSODIA** (R. Brown) is a genus of plants belonging to the natural order *Orchideæ*, and found naturally in New Holland. It thrives in sandy loam and moor earth, and only requires water when in a growing state.

**GLOSSULA** (Lindley). An orchideous plant indigenous to China, lately introduced to European collections. This plant is called *Glossaspis* by other authorities.

**GLOW-WORM**. A small luminous insect\*, belonging systematically to the order *Coleoptera*, al-

though destitute of wings or wing-covers, section *Pentamera*, family *Lampyridæ* and genus *Lampyris*, which see for the systematic characters of the insect. One species only of these insects inhabits this country, namely, the *Lampyris noctiluca*, which is to be seen amongst grass and low herbage upon banks during the summer evenings, emitting a beautiful clear greenish light from the underside of the extremity of the abdomen, not much unlike that of phosphorus. It is the female, however, which is generally observed to emit this light in such situations, the male being a smaller and more active winged animal, totally unlike his sluggish partner. Some of

The male and female Glow-worm.

our poets have indeed supposed that this was not the case, giving to the male the admiration resulting from this beautiful appearance: thus Cowper, in his verses on this insect, says

“this truth divine  
Is legible and plain.  
’Tis power almighty bids him shine;  
Nor bids him shine in vain.”

And Shakspeare, alluding to the supposed cessation of the luminosity before day-break, tells us that

“The glow-worm shows the matin to be near,  
And ’gins to pale his ineffectual fire.”

It is, however, to the females that these writers have alluded, and the especial possession of such a power by individuals of this sex has led to the idea that the light is given to them for the purpose of attracting the roving male and disclosing to him the retreat of his mate.

That the possession of this light is of far higher importance in the economy of the insect than the supposed use of which Cowper sings, viz.—

“To bid the traveller, as he went,  
Be careful where he trod;  
Nor crush a worm, whose useful light  
Might serve, however small,  
To shew a stumbling-stone by night,  
And save him from a fall,”—

cannot be questioned; and when we remember the propensity of many nocturnal insects to fly towards a light, and which is exhibited not only by moths but also by many species of beetles\*, we may, with Dumeril, regard this phosphorescent light as “the lamp of love—the pharos—the telegraph of the night which scintillates and marks in the silence of darkness the spot appointed for the lovers’ rendezvous.” It may, indeed, be objected to this supposition, that there are various other species of nocturnal insects which are in a condition similar to that of the glow-worm, namely, the males winged and the females apterous,—

\* Mr. Main states that the male glow-worms have been seen in such numbers as sometimes to cover a table round a lighted candle in an open room. And Mr. Bird, in his account of moths captured by means of a lamp near Reading, includes, “as might be expected, the male of *Lampyris noctiluca*.”—*Ent. Mag.* ii. 41.

and yet, being also night-fliers, the females are destitute of any light. But here the analogy will not hold in both cases; in the moths the males are furnished with beautifully feathered antennæ, and so long as we are ignorant of the uses of these organs, it is not too much to assert that they may give to their possessors powers of appreciation or senses which those species which have simple antennæ are destitute of; and this is the case with the male glow-worm, although in various popular works, lately published, these organs are represented as much feathered as in the moths.

In the "Journal of a Naturalist" we find the generally received opinion endeavoured to be supported by the structure of the thorax of the male glow-worm, which is so formed that when at rest no portion of his eyes are visible; but the head is margined with a horny band or plate, under which the eyes are situated, and which prevents all upward vision, as well as greatly to impede the view of lateral objects; so that by confining his view in his nightly flight to what is before or beneath him, his search is greatly facilitated. It is true that the structure of the thorax of the female glow-worm is similar to that of the male; but it is only when at rest that its position is such as is described by the author of the "Journal." The membrane which connects the head with the anterior cavity of the thorax is in these insects much more pliant and extensible than in any other beetles with which we are acquainted; so that when employed, the head is as much exerted as in other beetles; so that when taken in conjunction with the large size of his eyes, the male glow-worm possesses a greater field of sight, owing to the flexibility of the membranous neck, than most other beetles. But it has been further objected, that the popular theory cannot be maintained; first, because in the earlier stages of the existence of the female insect it is slightly luminous\*; and, secondly, that the males also possess in a small degree the same power. The principle of gradual development, however, is surely a sufficient answer to the former objection, and we cannot see why the circumstance of the males being luminous should be a reason why they should not be attracted by other lights;—moreover, why should not the female be supposed to possess a similar propensity of approaching luminous objects as the male? In some of the exotic species the males are as luminous as the females, and the latter furnished with wings; and can it be supposed that the latter would not be attracted either to a lamp or to the light of the male?

The habits of the glow-worm have been recorded by various authors; the most interesting accounts which we have met with are those given by Mr. Wilson, in his *Entomologia Edinensis*, by W. H. White, in the *Magazine of Natural History* for November, 1835. The latter gentleman having collected some females towards the end of June, confined them, with a male, in a glass jar, with sand two inches deep at

the bottom, covered with moss, kept damp. After various experiments, he discovered a female half buried in the shell of a snail (*Helix nemoralis*), in the act of feeding upon the inhabitant; he accordingly supplied his captives with snails, upon which they thrived well, eating for the whole day without intermission, after which they fasted for eight days. About the middle of July he observed one of the females depositing her eggs amongst the moss; a week after which she died—the remainder also died at the beginning of the following month. "The eggs," he proceeds, "were of a pale yellow colour when deposited, and instantly emitted light; and I found, when I had occasion to sprinkle the moss with water, that the eggs emitted a stronger light; they became a little darker in four or five days. On August 27th, the larvæ began to appear. They were rather lighter in colour than the eggs, but became gradually darker as they advanced towards maturity. They had, when young, the power of emitting light or otherwise at pleasure. In sixteen days three of the larvæ ceased to eat (snails?), and retired to one side of the jar for the purpose of moulting or casting their skins, in which operation they appeared to suffer much; they became very weak and languid, and ceased to emit light. The operation being at length overcome, two whole days passed before they appeared to have strength to partake of food; but after they had once or twice taken nourishment, they became more lively and vigorous, emitted a much stronger light, and seemed to make amends for their long fasting by eating, if I may so speak, with double voracity. On the 10th of May following (making a period of nearly nine months in coming to perfection) three of the larvæ ceased to take food, and, as I thought, to prepare for another moulting; which indeed was the case, but instead of a lively worm I soon found (on the 13th) that one of them had become a chrysalis, and the other two changed into the same state on the 15th. The chrysalis, at first, appeared of a yellowish colour, but soon deepened into a reddish-brown. In the course of ten days several other larvæ entered into the chrysalis state; whilst others, to my great astonishment, still continued in their larvæ state till the May following, making a period of one year and nine months; whether this was owing to any improper treatment, or whether they required longer time to arrive at maturity, a second experiment may be the means of convincing me. But to return to my chrysalides; the first, a female, arrived at perfection on the 30th of May; the second, a male, on the 3rd of June, and the third, a female, on the 5th. The skin of the chrysalis is so transparent, that the perfect insect, whether male or female, is easily distinguished through it."

The larva of the glow-worm very much resembles the perfect female in its form; it may, however, be distinguished by its larger size, and its colour, which is velvety black, with the posterior angles of the segments dirty red, and by the rudimental structure of its antennæ and legs; the former, instead of being composed of eleven joints, having only four; and the tarsi, instead of being five-jointed, consist of a single short piece. The mandibles, on the contrary, are much more developed in the larvæ than in the perfect insect, being sickle-shaped, and very acute in the former. The pupa resembles the perfect insect, except that the limbs are laid along the breast, and inclosed in a thin pellicle, the female pupa, of course,

\* It is evidently of the early and not the perfect state of the insect of which the author of the "Journal of a Naturalist" speaks, when recording their motions at the end of September, and which he regarded as indications of a migration to winter-quarters by the perfect insect, adding, that "if we conclude that the summer-light of the glow-worm is displayed as a signal taper, the appearance of this autumnal light can have no such object in view, nor can we naturally assign any use of it to the creature itself, unless, indeed, it serves as a point of union in these supposed migrations, like the leading-call in the flight of night-moving birds."

exhibiting no rudiments of wings or wing-covers, which are possessed by the male pupa.

The nature of the luminous matter of the glow-worm has much excited the attention of philosophers. By Forster it was stated that the light was so strong and continuous in oxygen gas, that one might read by it with facility; and M. Beckerheim not only ascertained the correctness of this statement, but also discovered that the insects were capable of living not only in the different gases (muriate and sulphurous excepted, in which they die in less than eleven minutes), but even in vacuo; also that hydrogen gas became detonating in consequence of the presence of these insects; that the light is produced by small luminous particles, which the insect can cover with a membrane, so as to stop the external appearance of luminosity; and that after the removal of these luminous particles from the body of the insect, without endangering its life, it has continued to live, but without any re-appearance of light. Dr. Caradori, an Italian chemist, instituted an extensive series of experiments, which are detailed in Griffiths's *Animal Kingdom*, upon the *Lampyrus Italica*, for which, however, we cannot devote more space than to give the following short particulars:—The phosphorescence is a property independent of the life of these insects, and it is attached rather to the degree of softness of the phosphoric substance, dryness suspending the light, whilst softening in water regenerates it, but only after a certain period—a remark also made by Reaumur and Spallanzani upon the *Phelades* and *Medusæ*. He also tried upon the *Lampyrus* and their phosphorescent matter the action of the different saline and spirituous fluids, in which they have exhibited the same sort of phenomena as the other phosphoric animals, the phosphoric matter undergoing a dissolving action only through the medium of water.

But phosphorescent matter is not of itself luminous, it being necessary that it should be brought into contact with oxygen; and Dr. Burmeister overcomes this difficulty by the following remark:—"If we imagine oxygen combined with the fatty substance or its albumen, respiration gives it luminousness; by means of respiration oxygen is deposited in the corporeal substance; each inspiration, therefore, makes the beetle shine; and, again, next to respiration the circulation of the blood appears to have considerable influence upon the light, for we know that the substance emits the light only when moist. Carus has also observed that upon each pulsation, and consequently upon each fresh wave of the blood, the light shines brighter\*."

It only remains for us to mention the species of these interesting insects. Hitherto one only has been decidedly found in this country. By Stewart and Marsham, indeed, the *L. splendidula* was introduced as a native species, but incorrectly; the specimens belonging to the latter having proved, according to Mr. Stephens, to be only a stunted specimen of *L. noctiluca*, our common species, and which appears to be generally distributed throughout England; near London we have found it at Combe Wood and Richmond Park, in Surrey, and it has been found on Kennington Common, at Hendon, &c.

There are, however, several other European species. The *L. splendidula* (found in the middle of Germany and south of France, and which is smaller than *L. noctiluca*). *L. zenckeri*, *L. Mauritanica*, and *L. seneki*, agreeing with our British species in the apterous condition of the female and full-winged males. In *L. hemiptera*, however, the male has truncated elytra, and the female is entirely apterous. Dejean has accordingly formed it into a distinct genus, named *Geopyris*; whilst in *L. Italica*, *Piedmontana*, *Illyrica*, and *Lusitanica*, the female does not differ externally from the male, both having wings and elytra, although some entomologists, as Rossi, Illiger, and Carns, speak of apterous females of *L. Italica*; but they have evidently mistaken the larva for the female. These species, with other exotic ones, constitute Dejean's new genus, *Colophotia*.—*Catal. des Coléopt.*, p. 301.

**GLOXINIA** (Heritier). A highly ornamental genus introduced from South America. Class and order *Didymia Angiospermia*, and natural order *Gesneriaceæ*. Generic character: calyx superior, in five nearly equal parts: corolla tubular, swollen, bent, limb obscurely two-lipped, four or five lobed; stamens included, with the rudiment of a fifth; filaments inserted on a disc upon tooth-like glands, fixed on the germen; anthers two-lobed; style with a double-plated stigma; seed-vessel two-valved. The gloxinias thrive in a light rich soil. Individual plants flower best. *G. maculata* is increased by dividing the root. *G. speciosa* flowers abundantly, and strikes freely by cuttings. This plant is constitutionally curious, as leaves taken off close to the stem, placed in soil, and placed in heat, will emit roots and a bud, which shoots up to form a perfect plant.

**GLYCYMERIS** (Lamarek; MYA SILIQUA, Linn.) The few species of this genus yet known, have been blended by previous authors with the *Myæ*, from which their hinge however clearly distinguishes them; they are doubtless allied to the *Solen* and *Saxicava*, from the first of which they differ, having teeth at the hinge; and from the latter by the ligament being placed on the shortest side of the shell, which is transverse, widely gaping on either side; hinge callous without teeth, and with externally projecting callosities. The animal is unknown, and only two species are described by Lamarek, inhabiting the North Seas. The genus has been confounded with several others, and much obscurity exists respecting them. Many of the species appear to have been described by Daudin under the name of *Cyrtoderus*.

**GLYCYRRHIZA** (Tournefort). A genus of European herbs, some of which are cultivated, as the common liquorice for instance. The genus belongs to *Leguminosæ*. Liquorice is much cultivated in Spain, whence our chief supplies are drawn: it has also for many years been partially grown in England, plantations being formed at Mitcham, Battersea, Fulham, and other places in the neighbourhood of London; and formerly it was cultivated to a considerable extent at Pontefract, in Yorkshire; Workop, in Nottinghamshire; and in other provincial districts. Stow informs us, that the "planting and growing of *Licorish* began about the first year of queen Elizabeth's reign." One hundred weight of the root will afford twenty-eight pounds of the extract, commonly known as Spanish liquorice, which, when purified, becomes much more agreeable in flavour, and is known as liquorice lozenge. It enters into the composition of several pectoral medicines, and is used to cover the nauseous

\* Handbuch der Entomologie, § 252, translated by W. E. Shuckard, under the title of "A Manual of Entomology, from the German of Dr. Hermann Burmeister."

taste of aloe and other drugs ; but its chief consumption is among the porter-brewers. By the analysis of Robiquet, it has been shown that the sweetness of liquorice depend upon a peculiar form of sugar, which he calls *Glycyrrhizin* or *Glycion*. The roots also abound in amylaceous fecula, and contain a new crystalline substance, and a resinous oil, besides phosphate and malate of lime and woody fibre. *G. fetida* differs from the other species, by having a very disagreeable scent : the whole plant, when bruised, exhales a fetid odour.

**GMELINA** (Linnæus). A genus of East Indian trees, introduced into this country within the last twenty years : class and order *Didymia Angiospermia*, and natural order *Verbenaceæ*. These plants grow freely in sandy loam, mixed with a little moor-earth ; and cuttings placed in sand under a glass, strike root readily.

**GNAPHALIUM** (Linnæus). A very extensive genus of beautiful and curious plants met with in every quarter of the globe. Class and order *Syngenesia superflua*, and natural order *Compositæ*. Generic character : anthodium imbricated, the inner scales channelled and partly coloured ; receptacle furrowed and downy ; florets of the ray imperfectly female and slender ; pappus hairy, rough, pencilled or feathery at top. This genus, called, from the firm texture and durability of the flowers, *Everlasting*, contained formerly many more species than are now enrolled under the above name. The new genus, *Helichrysum*, and many species of *Melalasia*, have been separated from *Gnaphalium*. They are cultivated in moor earth, and are easily raised from cuttings.

**GNAT**. A name applied to various small species of dipterous insects, having a long slender body and legs, and belonging to the Linnæan genera *Tipula* and *Culex*. More strictly, the name is given to such as are furnished with a long proboscis employed in sucking blood, forming the last-named genus, whilst, for the smaller species of *Tipulidæ*, the name of midge is more applicable. We would, if possible, wish that all the species of animals were furnished with vernacular names, feeling convinced that much more instruction is gained by the employment of such names, which, to a certain degree, familiarise the objects designated, and which is in fact the plan adopted in Germany ; but the poverty of our language will not permit this. Still there are instances in which vernacular names may be reclaimed, and this appears to us to be one of them. To the *Culicidæ*, therefore, we restrict the name of gnat ; and to the *Chironomî*, *Corethræ*, and other minute *Tipulidans*, that of midge.

We have already, in the article *CULICIDÆ*, given a short and generalised sketch of the characters and natural history of the family of the gnats. In the present article, therefore, we shall confine ourselves to those particulars which are at once brought to mind by the mention of the word *gnat*, namely, their blood-thirsty propensities, and the structure of the apparatus by which these propensities are indulged. In the generality of insects which fly by night, we perceive a general inclination to fly towards, and to be bewildered by light ; but this is not the case with the gnat. We have repeatedly watched its motions in a lighted room, and whilst the moth and the midge have been dashing round the candles, scorching their wings and burning themselves to death, the gnat has

been leisurely flying about the room in search of its prey, and at length settling upon our hand with a touch so slight as not to be perceptible. This latter circumstance, indeed, is so remarkable that it can scarcely be regarded otherwise than an instance of remarkable instinct. If it were, at such a time, to fly about with as loud a hum, and as blustering a motion, as at other times, its visit would at once be detected, and death or disturbance would be the consequence ; but instead of this, it exhibits in its coming as much wariness and care as a cat about to spring upon a mouse. We have, in the general article, *DIPTERA*, mentioned the remarkable circumstance that, amongst the whole order, it is only those species which subsist upon blood, that have the various organs of the mouth developed to their full extent. In page 288 of the present volume, we have given a figure of the mouth of one of these blood-sucking species, and requesting our readers to refer thereto, we will shortly describe the structure of the mouth of the gnat, which is similarly organised, premising only that its real structure has only been very recently ascertained, and that whilst Leuwenhoeck supposed it to consist of only four pieces, Reaumur of five, and Swammerdam of six, it is in reality composed of seven distinct organs, exclusive of the palpi ; hence the figures given by Reaumur, are somewhat inaccurate in their minute details. In the mouth of the *tabanus* we perceive a large fleshy sheath, with terminal lobes, but in the gnat this organ is greatly elongated, so as to form a tube, or rather canal, capable, however, of being bent in the middle, and furnished at its tip with two minute lobes or lips. The six lancet-like pieces described in the mouth of the *tabanus* exist, but under a more elongated form, in the gnat ; and the pair of large flat palpi are also present, but variously modified in their form, and composed of four or five joints ; thus in the male and female *anopheles*, they are as long as the proboscis, the two terminal joints being much larger in the males than in the females, whilst, in the true gnat (*Culex prope*) they are as long as the proboscis only in the males, and very much feathered, whilst, in the female, they are very short ; other differences exist in the other genera of the family *Culicidæ*.

When, therefore, the gnat has taken its station upon the hand, or other part of the body, and ascertained, by the delicate structure of the small fleshy lips at the extremity of the external canal of the proboscis, the part most fit for attack, the internal lancets are protruded from the tip to a small distance, and, by their conjoined forces, a puncture is made in the skin, without, however, being felt by the victim ; by degrees the lancets are pushed deeper and deeper into the skin, the outer sheath becoming more and more elbowed in the middle, the bent part being directed towards the breast until the lancets being entirely buried, the base and tip of the canal are almost brought together, the intermediate parts uniting and forming a straight line. Hence it is evident that the analogy supposed by Swammerdam to exist between this sheath or canal, “ and the silver pipes (*canulæ*) used by surgeons, through which they pass their lancets into parts deep-seated, in order to prevent their wounding any other part than that which they intend to cut,” does not exist ; nor does the blood run up this canal, but ascends by capillary attraction into the stomach by means of the fine lancets. All this time the action of the gnat is not perceived, nor

is it until after it has taken its departure, satiated with gore, that the irritating action of the fluid, which it instils into the wound, in order to cause the blood to flow more freely, begins to be felt. We believe vinegar applied to the wounded part to be a serviceable remedy in assuaging the pain.

**GNIDIA** (Linnæus). A genus of ornamental shrubs from the Cape of Good Hope. Class and order *Ocandria Monogymia*, and natural order *Thymelææ*. Favourite green-house plants requiring much care, as they are killed by either too much or too little water. Cuttings of the young wood root best. Moor-earth is most suitable for them.

**GOAT** (*Capra*). A genus of ruminant mammalia, agreeing with the rest of the order in their general structure, but differing in so many particulars, and corresponding so well with each other in the majority of these, as to form a very distinct as well as a highly interesting family. Of all animals which are reared in a state of domestication, goats are the most picturesque in their appearance, the most lively in their manners, and the most hardy in their constitutions. Of all four footed animals which have hard hoofs, they are the surest footed; and this agrees with their native localities. They are the inhabitants of the rocks, the tenants of the mountain-top, and the precipice, browsing on that vegetation which is inaccessible to any other race of ruminant mammalia. In this respect some of the antelopes approach nearly to them, as for instance the chamois, or rock antelope of the Alps; but fleet as that animal is, and great as is its power of endurance, it is by no means equal to the mountain goats. It is probably on account of the vigorous constitution of those animals and their consequent power of enduring the utmost severity of the elements, that the ancients chose *Capricorn*, or the goat, to represent that sign of the zodiac which the sun occupies during the greatest depth and utmost severity of the northern winter.

Goats, in one or other of the species, are found in almost every region of the world; and they are very obedient to climate in many of their appearances; but wherever they are found they are a lively, brave, and healthy race. Their skins are remarkable for the firmness of the texture, and the strength with which the hair adheres to them. Generally that hair is long and shaggy, but fine in its gloss, and remarkable for preserving that gloss for a long time after the death of the animal. In some peculiar climates this hair is longer and of finer staple, as in the goat of Angola, which country by the way is remarkable for the length and beauty of the hair in some other of its mammalia. In some other countries again, as for instance on the northern slopes of the Himalaya mountains, there are goats which are furnished with two sorts of hair, one which is rough and bristly, calculated for throwing off the heavy snows which fall upon their upland pastures during the winter; and another which is shorter, of finer staple, and superior perhaps to the covering of any animal for the purposes of domestic economy. The animals which are thus provided are the Cashmere goats, or rather the goats which furnish the materials of the splendid shawls known by the name of Cashmere; for the goats themselves are rarely met with on the south side of the summits, and will not live in the valleys or plains of the lower and warmer parts of India. The wool of those goats, which forms, as it were, their inner clothing, is not near so fine in the staple as the wool

of many of the sheep; but there is a durability, and also a facility of fixing permanent dyes upon it, both of which render it of great value in an economical point of view. And it may be said with truth that there is no tissue woven of any sort of material which lasts so long, preserves its colour so well, or is so difficult to be soiled, as a genuine shawl made of the hair of the cashmere goat. On this account these articles are esteemed the most valuable productions of the oriental loom; and as such they are favourites presents among persons of distinction in that country: the favourite abode of pomp and luxury; and though in point of beauty and design, and fineness of texture, many productions of the looms of Europe are superior, yet in durability the very best of them fall short of the genuine productions of India, if made of the unmixt covering of the shawl goat of the Himalaya.

Goats, in all the varieties of their species, are understood to be remarkably healthy and wholesome animals. Among their native rocks they browse upon vegetables much too hard for almost any other of the ruminant animals; and it is understood that scarcely any plant, be it what it may, is deleterious to a goat. It is also said that they are not only proof against the poison of reptiles, but that they feed with impunity upon those possessing the most deadly venom. This last is not very clearly made out, though it is by no means unlikely; because there are proverbs respecting it in some languages. Thus for instance, in the Highlands of Scotland, there is an old proverbial expression for gratuitous malignity, which states that it is "like the goat eating the serpent." As goats are more vigorous in their motions, and probably more energetic in their whole character than probably any other ruminant animals, the flesh of the full grown ones, especially the males, is more tough, and it has a peculiar flavour which many persons do not relish. Its colour is remarkable for depth, indicating that there is more blood in a goat than in almost any other animal; and it is remarkable as a physiological fact, that this general distribution of blood and consequent redness of appearance in the muscles of animals, is always in proportion to the degree of energy with which those muscles are exerted, or capable of being exerted. When prepared as hams the flesh of male goats, though exceedingly hard and peculiar in its flavour, is much relished by some persons; and in any one who wishes to "make a day" in climbing the rocks of a goat's country, there are few pocket companions more worthy of being recommended than some slices near the knuckle end of a goat's ham. At first indeed they look more like slices of flint stones, or rather of mountain jasper, than of any thing else, and they require some vigour in mastication. But, notwithstanding this, and notwithstanding their saltness and peculiar flavour, it is astonishing how those slices of goat's ham stimulate the salivary glands, moisten the parched throat, and allay thirst when one is breasting a steep mountain under the ardour of a mid-day sun.

The flesh of female goats when in proper condition is tolerably good; that of young kids forms a delicious and withal a savoury stew; and when goats are kept for the purposes of domestic economy, and the males are mutilated as is done with oxen and sheep, they get very fat, and their flesh is described as being excellent. The milk of goats is reckoned superior in many respects to that of any other animal. It contains less oil, and on this account it sits lighter

Four Horned and Common Goat.

upon the stomach. Hence consumptive people are not unfrequently recommended to go to the goat-feeding districts, as a dernier ressort against that most direful of human maladies. With them, however, it is the whey after cheese or curds have been made, and not the entire milk, which is recommended; and even then it is probable that the fine air of the goat-country exerts as salutary an influence as the supposed medicine; but whether this be, or be not the case, is not much worthy of inquiry; because if valuable life can be saved (and as consumption is a disease of the young, the life of consumptive patients is always valuable), any circumstance that may bring them to the pure air of those cliffy regions, which goats inhabit, is always worthy of being cherished.

It is a fact worthy of notice, that the remains of the goat, and also those of the sheep, have not been found in any of the accumulations of fossil animals; though, with the exception of Australia, which is very peculiar in its zoology, goats are found native in all the more extensive countries of the world. In all regions they inhabit the most wild and inaccessible places; and yet they seem to have a stronger attachment to the human race than almost any other animals; they are playful and familiar; and it is highly probable that the goat was among the first animals that man employed in a domestic state. An instance of this is mentioned by a very accurate naturalist, relative to the wild goats of the Alps: he and his party landed on a wild and romantic spot on the bank of the lake of Thun, where those animals are numerous, and left comparatively in a state of nature; but he and his companions had no sooner landed than these wild goats came bleating about them with their kids, and even entered the boat, and resisted being driven from it. They did this too evidently from mere attachment to the travellers, because the pasture was rich, and the said travellers had nothing in the shape of food wherewithal to tempt them.

The introduction of the goat and the ram into the zodiac by the very earliest astronomers, shows that the people who first cultivated the science of the heavens were familiar with these animals; and indeed there is reason to suppose that the human race, from very nearly the dawn of their history, domesticated and found advantage in those animals. The account given of the deluge in the book of Genesis, is too scanty for supplying any adequate materials for natural history; but it is recorded that the ark rested on the tops of the mountains. We have also evidence in Britain, and almost in every country, that the mountain tops were the habitations of men before they took possession of the plains; and that in those early times the plains were covered with thick forests, inundated with water, or so full of bogs and quagmires, as not to be fit for human abodes. In many places, both of England and of Scotland, we have evidence of early inhabiting and cultivation upon heights which are now bleak and wasted; and even the roads and stations of the Romans, though they must be referred to a comparatively recent period of history, are usually found upon the high grounds. In America too, when that country was first discovered by Europeans, the most civilised races of the natives were found upon the mountains; and generally speaking, when we look at the whole earth, we find that, with the exception of the lines of the shores, and the banks of the larger rivers, the people inhabited

the mountains, while the low grounds were abandoned to tangled forests and wild animals.

This circumstance naturally connects itself with the goat and the sheep as mountaineers, and renders it probable that both of these were domesticated at an earlier period than the ox, which, inhabiting lower down, may not have been brought under the dominion of man until the pastoral life had been partially changed for the agricultural. Accordingly we find that these animals make an important figure in the mythologies of many ancient nations. Pan, which is a symbolical personification of the productive energies of nature, was furnished with the attributes of a goat; in like manner the Lybian Jupiter was furnished with the horns of a ram. The *Ægis*, which was equally the breast-plate or shield of Jupiter and of Minerva, was originally nothing but a goat's-skin; and by the fable of those two divinities, the goat was thus connected with supreme power and supreme wisdom, which shows the estimation in which the character of the animal was held. Under the Jewish rituals the goat was an important animal, and used as the appropriate symbol of atonement in the splendid rites ordained by the Supreme Lawgiver himself.

The skin of the goat appears to have been early used as an article of clothing; and the first cloth, or rather felt, which was made by the northern nations, appears to have been chiefly formed of the hair of this animal, mixed with shorter fur, matted together, and stiffened with the gum of trees, so as to be proof not only against the weather, but in a great measure against the weapons of their enemies. This species of garment is very frequently alluded to by the ancient poets and historians.

The war tunics of the Cimbri, which, in their wars with Marius, are represented as being such strong defences, were of this material; and the Roman auxiliaries had winter dresses of the same, in Britain, and all the other colder provinces of the empire. Even when weaving from spun thread took the place of the more ancient matting, it is highly probable that the long hair of the goat was used in preference to the shorter wool of the sheep. We have further evidence of the early domestication of the goat, in the fact that all Celtic tribes, which are justly regarded as the most ancient races of many parts of Europe, bred and cultivated goats long before the introduction of sheep. In the Highlands of Scotland and in Wales, the goat was the original domestic animal; and in both countries there are many districts called by the name of *Gower*, which is Celtic for goat, and many families have the same surname, whereas no name of the sheep is used except in cases where the use of it is comparatively modern. All these circumstances render the history of the goat a highly interesting one; but it is long, and the details are hardly fitted for a work like the present, though a volume of great interest might be written on the domestic history of the goat.

Goats as a genus are distinguished from Antelopes by the bony nucleus, or core of the horns, being, in part at least, cellular, and the cells communicating with the frontal sinuses of the cranium. The horns are more or less angular, or ridged, with transverse knots and wrinkles. Their usual position is upwards, and backwards; they are found on both sexes; but on the female they are much smaller in size, and more smooth in their surfaces than in the males. The line of the forehead is a little convex; the eye is very

lively and expressive; the iris being generally brown or yellowish, and the pupil large and oblong, as in other grazing animals. There are no sinuses or openings under the orbits of the eyes, as there are in most of the deer and antelopes, neither is there any muzzle, the naked part being confined to a small space between the nostrils: the ears are narrow and rather rounded at the tips; the tail is short, usually naked on the under side, and frequently carried erect. In almost all the species the males have a long beard; and even in such as have the body covered with comparatively short hair, the hair on the throat and dewlap is long. The hair of goats is not coarse, but it is very strong, smooth, and straight in the staple; and in almost all the species there is a fine woolly down among the roots of the longer hair. This down, where it is in considerable quantity, is of great value in the arts; and indeed the whole covering of the goat is remarkable for its durability. The legs of goats are much stouter in proportion than those of the antelopes. They are furnished with a callous appendage at the joint, and the hoofs are high and solid. The females have two mammae forming an udder in the groin; they go five months with young; the female is capable of propagating at seven months old; and the birth usually consists of two kids, which are perhaps the most sportive of all young animals. The male does not come to perfect maturity until the expiring of a year; and then a single male is sufficient for a flock of a hundred females. At five or six, the male is reckoned old; but the full life of the goat may be estimated at about fifteen years. At all times, but more especially during the rutting season, he-goats emit a peculiar smell, to which the name of *hircine* has been given, from the word *hircus*, a he-goat. In the rutting season the males follow the habit of all gregarious animals, in battling keenly with each other for the possession of the females; and though their mode of conducting those battles of gallantry is very different from that either of bulls or of rams, it is still very characteristic as well as picturesque. Bulls attempt to gore and toss each other with their horns; and rams, retreating to a considerable distance from each other, return with so much acquired velocity, as sometimes mutually to fracture the skulls of each other, and when they miss their aim, they tumble and sometimes break their legs; goats, on the other hand, rise up in their combats, and throw their whole weight in a curious oblique motion, which is very effective, so much so indeed, that a goat is more shunned by dogs and other carnivorous animals than the larger ruminantia. It gives its stroke very suddenly, and as it generally delivers its whole weight with great impetus against the ribs of the enemy, its attack is equally severe and difficult to be guarded against.

The tendency of the whole race is to climb to as high situations as they can. In a state of nature the whole of them inhabit the tops of the mountains, probably nearer the line of perpetual snow than any other mammalia of equal size. In a domestic state they also seek cliffy places, from which they do not descend unless for the purpose of drinking; and where goats are kept they add not a little to the picturesque effect of mountain scenery. When mixed with sheep on the same pastures, they invariably take the lead, and their more timid companions generally follow in their track. They are bold, impudent, and exceedingly capricious; always on the alert, and

remarkably observant of every object around them; and if that which they see is novel or dangerous, they instantly put themselves in an attitude of attack. They are among the most sure-footed of animals, and can pass along ledges of rocks of very narrow dimensions, upon the brink of the most frightful precipices. If two of them meet in any such situation as that now noticed, where there is no room for either of them to turn, the one crouches down and allows the other to leap over it, after which it rises again, and both pursue their journey with perfect safety. Bingley mentions a case of two goats meeting on the *Torus*, or projecting round moulding of the ramparts at the citadel of Plymouth, where the footing was very narrow, and the rampart overhanging the sea; but the one contrived to crouch down, and allow the other to leap over it so that both pursued their dangerous journey in perfect safety, and in the presence of numerous spectators.

All their senses are very keen: they see to a great distance, and notice every thing around them; and their sense of smelling, though themselves smell strongly, is very acute. In feeding they are very indiscriminate; and many plants which are not only shunned by other ruminating animals, but act as poison to them, are not only eaten with impunity but relished by goats. There have been instances in which tame goats have chewed tobacco; and in the wild state they eat the most bitter and narcotic plants, such as euphorbium, hemlock, henbane, and even digitalis, without suffering any injury. Few plants are more disrelished by cattle than the common ragweed, and therefore the pastures on those lands in upland and humid situations, are very much infested by it; but goats clear it off, if allowed to browse the plants before they come into flower. There are many of the *compositae* which are the pests of our pastures, and which are, generally speaking, biennials, making roots the one year, and bearing flowers the next, which might probably be cleared off, by pasturing with goats at proper times. The alternation with each other of animals, one set of which can eat the plants that are disliked by another, is an important point in the economy of our grazing districts, though it does not appear to have received that attention to which it is entitled. Indeed those who devote their attention to the rearing of domestic animals for profitable purposes, in general so confine themselves, both in theory and practice, to one species, that they neglect all others, and thereby seriously injure, and sometimes actually ruin the pasture grounds. It will be readily understood, that if a pasture land abounds in a plant which is disliked by any kind of grazing animal, that plant will be left, while those upon which the animal feeds are eaten up; and by this means the plant which is injurious to the pasture will seed and multiply, and in time overrun the ground, and choke and extirpate those other plants which are accounted more valuable. There is not the least doubt that in this way many of the upland districts of the British islands have been converted from grass land to heath, and thereafter followed the natural progress from heath to peat, in consequence of having been grazed by black cattle only. In those districts where sheep-grazing has been introduced, which, in the north at least, is a much more recent species of grazing, the quantity of heath has diminished; though in the more steep and wild places the sheep tracks have opened the surface to the rains, so that entire mountain sides have been

swept down to the naked rock, and ruined by the debris and rubbish the meadows at their bases. In situations where there is also a sprinkling of goats, it does not appear, at least so far as our observation has gone, that either of these consequences takes place, at least anything like so speedily; hence the admixture of cattle, sheep, and goats, and the judicious adaptation of the numbers of each to the natures of the pastures, is a point well-worthy the utmost attention of those who are proprietors of our mountainous districts, or otherwise take an interest in it. If the habits and feeding of useful animals, and the nature of soils and climates, and the progressive history of their vegetation were a little more studied, it would be all the better for the country; for there is no doubt that this species of ignorance does more real injury than is generally believed.

If plantations are an object, as they always are near the sea, for the sake of the bark and charcoal which can be afforded by judicious coppice cultivation, goats cannot be introduced without occasioning mischief, in consequence of the proneness which they have to bark the trees in winter, and gnaw the buds and twigs in the spring.

All the species of wild goats, which are not indeed very numerous, are remarkable for their activity among their native rocks; and though in forward running they are not probably equal to many of the antelopes, their single bounds, and the situations in which they take them, are superior to those of any other animals. If there is the least hold for their feet, so that they can get a point of rest for an instant, and thereby acquire an impetus, they will ascend a perpendicular wall or precipice fifteen feet in height; and it is astonishing how little hold will sustain them, and how speedily they will renew their leaps. It is generally said, and the saying is probable, that when they do lose their balance, and fall from the precipices, they contrive to fall upon their horns, in the same manner as a cat alights on its feet, and that they thus can tumble from a height of fifty or even a hundred feet without sustaining the slightest injury. Those which are found in the more elevated and rocky mountains, are represented as being able to ascend a considerable way between the perpendicular sides of a ravine. How they do this, and contrive to bound from side to side of the chasm, is not easily explained upon any principle of common animal mechanics; but it has been so frequently stated by authors whose descriptions are generally to be credited, that it cannot well be denied. How far the elasticity of the horns may aid them in this singular species of ascent, is not a matter that has been determined, or one which is easy to determine; but still the goat does ascend by leaping against one of the opposing faces of the rock, and alighting on the opposite face; so that the whole of the motion bears some analogy to an oblique billiard ball striking alternately on opposite cushions of a table, though the horns strike the one side and the feet the other. How these act so as to give an upward motion to the animal is a point not easily determined; but it is one which is worthy of study.

The boldness, dexterity, and hardihood of the goat among rocks, renders the wild goat one of the most hazardous species of game for the mountain hunters. They are exceedingly vigilant; and when alarmed or rendered suspicious, they can escape upwards, and they are said sometimes to throw themselves down upon the hunters, and tumble them upon the rocks,

in which case the hunter is dashed to pieces, while the mountain goat falls on its horns, and escapes unhurt.

Goats utter various sounds according to their age, and the feeling with which they are impressed at the time. The kids or young ones bleat, and their bleating, though sharp, is not unpleasant. When the older ones are alarmed, they utter a peculiar sort of whistle; and their general sound when preparing to repel danger is an indescribable sort of spluttering. In those wild places the females are strongly attached to their young ones; and a she-goat of the mountain tops can defend her kids from the wolf and the eagle with equal success.

Altogether they are animals of great interest, whether we regard their picturesque form, their vigorous action, or the readiness with which they can be domesticated, and the strength of their attachment to man when they are in that state. There is another point connected with the domestication of goats which is worthy of attention; and that is the great proneness which they have to break into varieties, according as their pastures differ. This tendency is one of the most remarkable evidences we have of the capacity of domestication in animals; and it is remarkable that the most domesticated variety differs from what we consider the unbroken natural species; it is always the more gentle in its disposition. Some remarks on this subject will be found on looking back to the article CAT, in a former part of this work; and we may repeat, that animals of that species which differ the most from the common brindled wild cat, such, for instance, as the three-coloured tortoise-shell cat, and the cat of Angora, are the most gentle in their manners. It is exactly the same with goats; and wherever there is a great departure from what is considered as the wild type, there is a corresponding gentleness of manners and attachment to mankind on the part of the animal.

The species of goats are but few compared with the numbers of the animals, and their general distribution over the globe; and from the tendency above mentioned of breaking into varieties, it is not very easy to say which ought and which ought not to be considered as a species. We shall therefore confine our observations to those which are the most definitely ascertained.

THE WILD GOAT (*C. Ægragrus*), is generally understood to be the parent stock of all the domesticated varieties of goats, much as these differ from each other

Syrian Goat.

It is the paseng of the Persians, and the bezoar goat of some other eastern nations, a concretion called bezoar being sometimes found in its stomach. The

horns of this species are of a brownish ash colour, uniformly arched backwards, but little divergent, and with a slight recurvature toward the points. In their section, they are compressed laterally, with sharp angular edges to the front, and with a sort of furrow which renders the edge sharper. These horns make an angle with the frontal bone; and are marked with projecting tubercles, between which the surface is slightly striated. Some of the authorities describe these tubercles as increasing with and indicating the age of the animal, but the point is not fully ascertained. Indeed the animal is naturally so wild, and can make its escape so readily, in places where it is not so easily followed, that it cannot be subjected to very accurate examination. On the posterior edge the horns are rounded; in the male they are sometimes three feet in length; but they are usually smaller in the females. The general colour of the male is greyish brown, with a dark line along the back and a black tail: the front of the head is blackish, darkest towards the nose, and reddish on the sides: the beard and long hair on the throat are reddish brown. The female is smaller than the male, and paler in the colour.

The wild goat is chiefly found on the eastern mountains,—in those of Caucasus, Persia, and various parts of Hindostan. That it exists in Europe is not very clearly made out. The ibex inhabits some of the more lofty mountains, where there are abundance of domesticated goats; and as the domestic he-goats breed readily with the female ibexes, it is very probable that those specimens, apparently intermediate between the common goat and the ibex, which have occasionally, though rarely been met with, are only hybrids between the wild and the tame goat. Indeed both the wild goat and the ibex vary so much in different countries, that is not very easy to draw a clear and satisfactory line of distinction between them. Indeed direct crosses between the domestic goat and the ibex are not uncommon in Switzerland; and the males of this cross are not only capable of breeding back to the pure blood of the goat, but are much esteemed for that purpose, as being larger in size than he-goats of the pure breed. Indeed it is probable that there is no muleism in the matter; but that the ibex and the goat may breed freely, so as that the mixed progeny may among themselves be prolific; for, of all the larger domestic animals, goats are probably the most free breeders.

The great distinction of the species is in the horns, and these are gradual. The ibex of the Alps has the horns remarkably square; that of Caucasus has them more rounded; while the Abyssinian variety makes an approach to the mountain wild goat, and that again to the domesticated ones.

In animals which are so flexible to climate, it is not easy to establish either a local or a progressive history with any sort of accuracy; and, therefore, we must either adopt the plan of endless detail, naming the goat of every locality, which is at once the most useless of all operations in natural history, or we must be contented to mention only two or three of those which have the most striking differences; and they are all different in country as well as in appearance, except in so far as they have been transported from one locality to another. In this respect the removal of goats does not appear to be so successful as that of some other animals. It is generally understood that the goats of the Himalaya will not live

even in the most hilly districts of peninsular India, although the temperature there is said not to be very different from that of their native mountains. The vegetation differs very greatly, however; for, when we ascend the Himalaya as far as the region of the native goats, we meet with a vegetation which is quite European in its character; whereas, in the south of India, the mountain jungles are in part at least composed of bamboos. There is another thing. The goats of the Himalaya, especially those most valuable ones which inhabit the northern slopes of the mountains, and which are said not to be met with any where to the southward of the summits, inhabit

Jemlah Goat.

a country rendered moist from the stores of snow on its mountain tops, as well as occasional showers purging the summer. In the south of India, on the other hand, both in Dukhun and in Mysore, but more especially in the latter, there are many of the more elevated districts in which there is no rain for a considerable part of the year, and where the monsoon sometimes misses, and there is no rain for two years. Now, the Cashmere goat, or shawl goat, as it is called, is an animal well provided, by the nature of its covering, for enduring changes of the weather, and especially the falling of rain, and, from being thus qualified, it is not adapted for the burning drought which sometimes visits the central parts of southern India, above the Ghauts or passes of the mountains. Some specimens of this far-famed goat, which, after all, is merely a variety of the common one, have been brought to Europe, and, both in England and in France, they have bred freely. In 1828, a Mr. Tower obtained from the Society of Arts in London their large medal, for having produced a goat's hair shawl equal to those of Cashmere, though both the growth and the manufacture of this country. This gentleman kept his Cashmere goats on a farm in Essex, and, from four first imported, his flock amounted, in a few years, to more than two dozen. We believe that those goats did not feed upon the rich pastures, or relish the vegetation of the ordinary grazing-grounds, whether native or exotic. The dry common was their favourite place of resort, and their most common food was furze, the prickly shoots of which they preferred to every other vegetable.

Considerable attention was paid to the keeping of these animals, and the fine wool was obtained by combing their common, or longer hair, with an instrument not very unlike the currycomb used for trimming horses. We believe that the fine wool is

procured in the east by a process nearly similar ; and it is possible that the fact of its being perfectly ripened on the back of the animal may contribute to its superior strength. It does not appear that the long hair is cast at the same season.

This experiment, and we believe those made in France have been as successful, from many circumstances connected with it, is well worthy the attention of those who cultivate natural history with a view to the promotion of domestic economy. At one time, it was very generally understood that the Merino sheep, producing the fine wool, could not be profitably bred in any part of Europe except Spain. It has been found, however, that the produce on the sandy plains of Saxony is finer than that from the original Spanish stock ; and so useful has the discovery proved, that in very many of the dry and sandy districts to the northward of the Carpathian mountains it has completely changed the character of the people's economy. In a great part of Poland, where woods are comparatively few, where the soil consists of sand and gravel, containing no mines, and where the people must, in consequence, subsist entirely on the surface-produce of the ground, that ground had been completely worked in tillage until it became comparatively unproductive, unless at a few spots advantageously situated. The first consequence of this exhausted state of a country is the falling off in the food of domestic animals, and a consequent diminution of their numbers. This, of course, diminishes the quantity of animal manure, and that diminution immediately tells upon the land in inferior crops. When this progress begins, it is of a growing nature ; and therefore there is not, in the power of common agriculture, any means of hindering it. It is the case with several of the poor and dry districts of England, which are far from fuel, and deficient in manure ; and, though it is probable that the whole is in a state of improvement as regards the cultivation of vegetables, it is highly probable, nay, absolutely certain, that many parts of it are fast declining in value. Now, we know no means by which calamities of this kind can be arrested upon the large scale, and the land brought back to fertility for tillage, but the depasturing of it by some species of ruminating animals. Hence it becomes very desirable to know, not only what ruminant can be bred with present advantage in any particular district, but what can, while it compensates the breeder for his labour, turn the tide-ruin from the land, and gradually bring it back to fertility.

The case of Poland, to which we have above alluded, and also of the light lands on both banks of the Oder, form experiments exactly in point. In very many instances, the farmers, especially those who migrated from Saxony, when so much of that state was annexed to Prussia, have ceased to be grain farmers. Indeed, they found the crops unprofitable, except on the rich bottoms, to which the substance of higher grounds is washed by the rains of autumn and winter. Thus they became shepherds, naturally imported the same valuable breed of sheep which had already succeeded so well in Saxony ; and thus, while their wool is a more marketable article, more easily carried to market, and really more profitable than the corn, a sword is gradually coming over many places, which, when the scanty crops of rye were cut down, remained nearly plantless throughout the year. As this has succeeded so well in the case of sheep, it would be at least worth while to try

Cashmere goats upon the bleak and dry commons of this country, because there is a point of sterility in such commons at which any attempt to graze them with sheep is a failure.

These remarks apply not only to the Cashmere goat, but to almost every species of the genus ; and any one who considers that we have, within the four seas, a thousand climates, and all varieties of soil, from the rich meadow, which scarcely any continuance of tillage will exhaust, to the plantless mountain-top capped with snow, it is not easy to point out from which place of the world a ruminating animal could be brought which would not find some spot in these kingdoms very nearly corresponding to its native locality.

This is one of the strongest inducements which can be held out for the scientific study of this useful class of animals in conjunction with the nature of those places of which they are natives, or to the circumstances of which time has, at all events, tempered them. Probably we shall resume it a little when we come to the article RUMINANTIA ; but it is an extensive subject ; in many respects it is a new one ; and we cannot resist the present opportunity of recording our opinion of its usefulness, and earnestly recommending our readers to promote it by every means in their power. Having done so, we shall return to say a very few words on the varieties and species of goats, which are in themselves matter of far minor importance.

Egyptian Goat.

THE COMMON GOAT (*C. hircus*, is found in almost every quarter of the world, though in considerable variety in the different districts, and almost every one is so familiar with its most common form, that a description of it is not necessary. In many parts of continental Europe, and those especially in which other means of subsistence and wealth are the most difficult to be procured, the common goat is of very great service. On the poorest pastures she-goats yield a good deal of milk, which, though it contains but little cream or oily matter, is both agreeable and wholesome. We mentioned already some of the uses of the bodies of these animals ; and we may add, that the skin is an article of great commercial value. That of the kid is the most flexible, the most handsome, and the most durable for light gloves and shoes ; and this answers well with the condition of kid's flesh, and the rapidity with which goats breed, that flesh being without any of the rankness and

hardness of that of the mature animal, and being in fact more juicy and delicate than lamb. In foreign countries, where goats are abundant, the skins of the mature ones are used for many purposes, being a substitute, and a very durable substitute, for various kinds of cloth. There is no skin which takes so fine a dye as goat-skin, and there is none of the same lightness and flexibility which is so strong. In Turkey, and other parts of the East, it is still used for the manufacture of what is called Turkey or Morocco leather; and though European manufacturers do what they can to produce imitations in sheep-skin, those imitations are vastly inferior to the genuine article.

Goat-skin is used for many purposes in the army. It forms the cover of the dragoons' holsters, and used to form the knapsack of the foot soldier. The whitest wigs, those which give a lawyer a sufficiently snowy head without the unseemly addition of hair-powder, are made of goats'-hair, bleached and baked; and there is no doubt but that an excellent wool might be obtained by combing any variety of the domestic goat at the proper season of the year. The goats of Angora, and of many parts of Syria, produce that hair which is spun into camlets, of which the consumption was at one time very great. They are now imitated with sheep's wool of a peculiar staple, spun in such a manner as to give the threads the hard appearance of the genuine camlet wool of the Levant; but the best of these imitations are vastly inferior to the real camlet, both in the fastness of their colour and in the time that they last. If a man gets a real camlet cloak, which has actually grown on a Turkish goat, he not only has a good garment for life, but may have a tolerable one to leave to his heir; whereas a single season, and often a single day, will, in many instances, completely spoil the best imitation.

In general, there is a traceable resemblance between the domestic goat and the wild goat of the mountain rocks; but the male is of inferior size, and the hair is of coarser texture, which is perhaps one of the most remarkable instances of change in the clothing of an animal. It is one, however, for which we ought to be prepared; for domestic goats, though they are principally attended to in upland districts, never are so high-on the mountains as the wild ones. They are thus subjected to a less rigorous climate; and the tendency of a warmer climate is always to roughen, as well as to thin, the hairy coverings of animals. The horns, even in those varieties which most resemble the wild ones, do not incline so much backwards, and the tips are very generally turned outwards. The colours of these are various: some are black, or blackish brown, while others are sand colour, and others again are black and white. Those which may be considered as deviating the least from the natural state and habits of the genus, have the hair long and shaggy, although of fine staple, and remarkable for its strength; but there are others in which not only the shape, but even the number of the horns, differ from those of the wild goat; the coverings of their bodies are smoother, and tints of brown and reddish are blended with their colours. Some, also, have the ears pendulous; some are without horns; and some have more than two horns, of which *ast the Plate, GOATS*, contains a specimen. To enumerate the various races of goats, all of which are, more or less, referrible to the same type, would be an endless, and not a very instructive task. The Persian goats have horns resembling in form those of

the wild goat, but smaller in size. These goats have the ears small and erect, and a conspicuous tuft of hair between the horns. The general colour is brownish ash, with rust-coloured points to the hairs. The Welsh goats, which are so well known as to be identified with the principality, are of large size, and the hair fine and long, and usually of a white colour. The horns of the males are of large size, often more than three feet in length. They stand nearly vertical in the greater part of their length, but bent outward at the tips. The dwarf goat is understood to be originally from western Africa, but it has thriven well in South America and the West Indian islands, where great numbers are to be found. They are, however, very much intermixed with other breeds, but always have a covering of short and close hair. This hair is varied with fawn colour and white on many parts of their bodies; but the produced hair on the beard and neck, and also the tail, is not unfrequently black. This variety is commonly without horns, and the ears are small and erect. It is very liable to break into differences, so much so that instances have occurred of the females having four mammae. This race of goats is, generally speaking, more timid than most of the others. It is not a little remarkable, that the goats in Sweden, and those in the mountainous parts of Spain, bear a close resemblance to each other. These are generally Without horns, with long hair and upright ears.

Angora Goat.

In central Asia, where goats are much used in a domesticated state, there are many varieties, one of the most celebrated of which is the Cashmere goat, to which we have already alluded. It is remarkable for the length, whiteness, and silky texture of its hair. The horns are not so rugged as those of the common goats; and the ears are generally dark-coloured, and partially pendulous. The legs are very cleanly made; and altogether they are handsome animals. The under fur or wool, which is the valuable part of the covering, is white, readily dyed, and retains its colours with great tenacity. It is understood that this breed is confined to the higher parts of the Himalaya; and that when the valley of Thibet is arrived at, there is an inferior breed, which is, however, still valuable as a wool goat, though its wool is not of the same delicate texture as that of which the fine shawls are made. This breed has been introduced into France. The horns are not so brown as those in the former; the ears are less in size, and the legs are stouter in proportion to their length. The colour is more subject to variation from dark spots than that of the true Cashmere goats. The goats of Angora (see the cut) have the hair white, and generally long and very

soft; and their general expression is slightly that of the sheep. Their ears are large and of a buff colour; and the horns are upright in the males, but smaller and bending downwards in the females. The Syrian goat (see the cut on page 643) also has the hair long, but not so fine as that of the Angora goat. The Egyptian goat more resembles the goats of Europe (see cut, page 645). All these varieties have small horns. Some of the goats farther to the east have the horns much larger, as the Jemlah goat (see page 644).

The other members of this genus, which may be considered as differing in certain respects from the goats of common language, and partaking in part of the characters of the antelopes, are those to which the general name of *Iber* has been given, but which has been qualified with different names in the species or varieties which are found in different parts of the world. Of these, one at least is European, one African, and one Asiatic; though the African one is met with in some of the adjoining parts of Asia, as for instance in Arabia. They are all mountaineers, and inhabit fully as high as those species of which the wild goat is considered as the stock and type; but they are less numerous in individuals than the goats, if we include the domesticated varieties along with the wild ones.

THE IBEX (*C. Iber*). This animal is found, though rarely, in the Alps, still more rarely in the Pyrenees, and, as it is understood, in some other mountainous parts of Europe and Asia. The male has considerable resemblance to the goat, but has the head smaller in proportion, though the whole body is larger. The eyes of this species are large, round, and brilliant, and even fiery in their expression. The length of the full-grown male is about five feet, the height at the shoulder about two feet eight inches, and that at the rump about two feet ten inches. The horns are flat, with longitudinal ridges on the sides, and transverse furrows across; they incline backwards and outwards. It has been said that the transverse ridges of the horns mark the age of the animal, but the fact is not absolutely made out. When young, the ibex is light greyish ash, but the colour deepens when it comes to maturity; and it is then brownish in summer, and greyish in winter. Those animals have but little beard, not much dewlap on the throat; and their hair is at no time long and shaggy, but resembles that of the deer more than the goats. The dorsal line on the back is darker coloured than the rest of the covering, with the exception of the face, part of which is nearly black; the ears are small and erect; and the whole air of the animal is lively and vigorous. The ibex being esteemed a valuable prize by the Alpine hunters, has been almost exterminated on the Pyrenees; and it is comparatively rare on the Alps, except in some of the more elevated places of the Tyrol. The female when full grown has the horns about as large as those of a three year old male; and the prevailing colour is brown. The rutting season is in autumn, at which time the scent of the males is peculiarly strong. The sexes remain in company during the winter; but, as the spring advances, the females retire to the cover of the Alpine thickets, where they produce their kids. This takes place about April or May, and the young are very active, and carefully guarded by their mother.

The hoofs of the ibex are very firm in their texture, and are furnished with a sharp margin, like those in the chamois. The animals are very expert in leaping,

and the time between the leaps is so short that the animal resembles an elastic substance taking various bounds from mere elasticity, instead of an animal which has to renew its effort every time it touches the earth. When pursued they take to the glaciers, along which they can bound with great rapidity, and clear chasms of a good many feet, though in general they do not resort to such surfaces, as they furnish no food. They are gregarious, though the flocks seldom exceed a dozen, and rarely amount to so many, even in those places where the remains of the race are supposed to be most abundant. During the night, in stormy weather, and generally speaking in the winter, they resort to such woods and copses as are found in elevated places; and it is understood that they subsist, in part at least, upon twigs and bark, and even upon lichens. In fine weather they resort more to the open places, and are more scattered. The months of August and September are those in which they are in finest condition, and most earnestly sought after by the hunters. The flesh of the old ones is inferior to venison, but superior to that of full-grown goats; and that of the young is peculiarly fine. Altogether the ibex is an interesting animal, and it is not the less so from being found only in the most wild and inaccessible places, and being sought for at the very extreme of peril to the hunter. One almost regrets the success of ibex hunters, notwithstanding their boldness, and the hazards to which they expose themselves; for the animals are too fine for being upon the verge of extirpation.

THE IBEX OF CAUCASUS (*C. Caucasica*) inhabits the mountains after which it is named; and though it, upon the whole, has a considerable resemblance to the ibex of the Alps, there are differences between them. This species is broader and shorter in the body; of a darker brown colour on the upper part, and whiter on the under. The head is generally greyish, but with a black space round the mouth. The chin and upper part of the throat are whitish grey, but the breast is black, as is the dorsal line. The fronts of the legs are black, and there is a whitish streak on them behind; the horns are nearly two feet and a half in length, of a dark brown colour, and very solid. The hair, though not so much produced, is hard and rough, and thickly interspersed with grey wool among the roots. The females are smaller, and have their horns less; and in the male they are not so much roughened by transverse furrows and ridges as in the common ibex. The characters of the two species are very similar, and indeed it is doubtful whether this be not the more energetic animal of the two. Hitherto it has been observed only in the elevated parts of the Caucasus, but it is highly probable that it may exist in some of the other elevated mountains of central Asia.

THE IBEX OF ABYSSINIA (*C. Jacla*). This species, which appears to have been known to some of the ancients, and which is mentioned by some of the Jewish and Arabian writers, differs more from the two formerly mentioned species of ibex than they do from each other. It stands higher on the legs; and the hair on the greater part of the body is shorter and closer. The general colour is dun; and there is little beard on the chin of the male; but the throat and upper parts of the fore legs are furnished with long hair. The backs and fronts of the legs are marked with short and dark lines. The ears are very small, the forehead is rounded, the horns are larger than

those of the ibex, and each one is curved to nearly half a circle. They have a round edge to the front, and numberless small transverse furrows on the sides. This species, of which the natural history is not very satisfactory, is understood to be abundant in the mountains of Abyssinia and the elevated grounds on both sides of the Red Sea, so that it does not inhabit such elevated places as any of the other two species. We are, however, in want of further information respecting the wild animals of those parts of the world.

Such are a few particulars in descriptive history of those species of the genus *Capra* which appear to be best made out. Many others have been mentioned by different describers; but the tendency which the whole genus has to break into varieties, both of size and colour, renders it necessary to speak of them with a good deal of caution. It is possible too that where wild ones meet, there may be numerous crosses between them, which further adds to the confusion. Notwithstanding these circumstances, the goats are an interesting genus of animals, both because they appear to have been among the first, if not the very first, ruminating animals which man domesticated; and also because they take up their habitation in those places of the earth which, though they are the most sterile, are at the same time the most sublime; and there is a spirit about the animals themselves which increases their interest.

GOAT-MOTH (*Phalæna, Bombyx, Cossus*, Linneus). *Cossus ligniperda* of modern entomologists. The name of one of the largest species of British night-moths. It is of a grey colour, with numerous dark spots and lines on the wings. The larva, which is supposed to have been the celebrated cossus of the Roman epicures, feeds on willow-trees, which it bores in all directions, sometimes rendering them so weak as to be overthrown by the first high wind. This larva is a large fleshy looking grub, and emits so strong a scent, that its presence in a tree may be known to persons accidentally passing, hence the origin of the English name. It is this insect which has been the subject of a series of the most elaborate dissections by the celebrated Lyonnet, and which have rendered his name immortal.

GOBIOIDÆ. The Goby family, the twelfth order into which Cuvier divides the *Acanthopterygii*, or fishes with spinous rays to their fins. They belong to that division of the order which has a portion of the bones of the pharynx formed into cells partly cartilaginous and fitted with covers, by means of which a portion of water can be retained for the purpose of moistening the gills. All the fishes which have this peculiar form of the mouth, are remarkable for being able to live some time without water. They are, generally speaking, ground fishes, capable of crawling about from pool to pool, when the tide of the sea or the flood of a river leaves them; and some of them are capable also of making their way across the banks, and even of performing short journeys upon land. An account of one of the most remarkable of these will be found in the article ANABAS.

The Goby family have the spines of the dorsal fin slender and flexible, they have the same internal structure, namely an intestinal canal without cæca, and no air bladder. There are several genera in the family, one of which will be found noticed under the article BLENNY, and another under the article ANABAS, and others in the words referred to in those articles.

Though curious in their habits, none of these

families are very interesting in an economical point of view; and they are, generally speaking, very small in size.

THE TRUE GOBIES (*Gobius*) have the ventral fins united throughout their whole length, so as to form a concave disc. The body is lengthened; the head of moderate size; the cheeks puffed out, and the eyes near each other; they have two dorsal fins, of which the one is long. In general they prefer places having a clayey bottom, in which they excavate passages for their winter habitations. In spring they prepare a sort of nest, in which the spawn is deposited and fecundated, after which it is covered with sea-weed, to preserve it from the attack of enemies. There are a good many species inhabitants of the European seas, none of which are of much size, or any value, except as food for other fishes.

The black Goby, or rock fish (*G. niger*), is rather a rare fish on the British shores; and the following is the description of it, as given by Mr. Yarrell, from the manuscript of the late colonel Montagu. "The head is large, the cheeks inflated, and the lips very thick; the mouth is wide, and furnished with numerous small and very short teeth in several indistinct rows in both jaws; the under jaw is roughened by them like a rasp; the eyes are high up on the head, and approximate; the upper part of them dusky, partaking of the colour of the head, the lower part of the irides golden: between the eyes are two small pores, the anterior one more than double the size of the other, but not distinguishable without the assistance of a lens: the nostrils are placed before the eyes, on the outside of each of which is a small fleshy appendage, rather elevated: the cheeks and opercula of the gills are furnished with lines of very minute papillæ, which appear like spines; most of these lines are transverse, but some run longitudinally, observable only with the aid of a glass. On the top of the head a longitudinal sulcus runs as far as the commencement of the first dorsal fin. The colour is uniformly dusky in the matured fishes, except from the chin to the vent, which is whitish, with some deep purplish black between the gills beneath; the ventral fins usually more or less black. It is, when fresh, covered with a thick mucous secretion; but after having been in spirits, the fish becomes extremely rough to the touch if rubbed the reverse way. This roughness is occasioned by the scales, which are large in proportion, being ciliated at their free edges.

"The ventral fins, which supply the great generic character, are connected, forming a funnel-shaped appendage of twelve branched rays; and the anus is furnished with an elongated tubercle. We never could discover that the black goby ventured into fresh water, and with us certainly spawns in the sea. With respect to the union of the ventral fins, it would seem to be for the purpose of forming an instrument of adhesion; but in no instance have we observed that they adhered either to rocks, or to the bottom of the glass vessel, in which they have been kept alive for several days."

This species is found on the rocky shores, in all parts of the country, from Cornwall to the Orkney islands. The spawn is deposited on rocks; the young are plentiful in the summer, and the full grown ones do not exceed five or six inches in length. The ventral fins form a perfect disc.

The double-spotted Goby. This species has been named by Mr. Yarrell, from two dark spots on each

side, the one under the first dorsal, and the other near the base of the tail. It is a small species, only between two and three inches in length. It is found on many parts of the coast. The body is brown.

*The spotted Goby.* This species when full grown is about three inches in length; and is plentiful in the estuary of the Thames; but it is not used for any purpose except as a bait for other fish. The ground colour is pale yellowish white, freckled with small rust-coloured spots.

There are several other species or varieties; but they are too minute and unimportant to be entitled to any particular notice; and we shall mention the more interesting of the remaining genera that compose the family under their generic names.

**GODWIT (*Limosa*).** A genus of *Echassiers*, or stilt birds (*grallidæ* or waders), and which belong to the true marsh birds. They are of the *longirostral*, or long-billed division; and both in their structure and their habits, they hold a sort of intermediate place between the snipes and the avocets.

The generic characters are: the bill very long, soft and flexible throughout the whole of its length, slightly recurved or turned upwards, depressed, and flattened toward the tip. The two mandibles of the bill have furrows toward the sides. The upper mandible is longer than the under one; and there is a sort of knob on the inner side of it at the tip, against which the point of the lower mandible acts; and thus, though the bill is soft and flexible, it is capable of breaking a small shell, or bruising any of those little animals upon which the birds feed. The knob in the godwits is not, however, so well developed as in the snipes, and this forms one of the characteristic differences between the two genera. The nostrils are pierced in the furrow, and partially closed by membrane. The legs are long and slender, and bare of feathers to a considerable distance above the tarsal joint. There are three toes to the front, and one to the rear; the three front ones are rather long, and the middle and outer ones united by membrane as far as the first joint. The hind toe is articulated upon the tarsus higher up than the others. The wings are of mean length, best adapted for rapid and whirling flight, the first quill being the longest.

Marshes and the oozy banks of streams are the favourite haunts of the godwits. They are never to be met with in the open country, or on the margins of clear waters which have pebbly banks and beds. They are more aquatic in their habits than the snipes and woodcocks, but less so than the avocets, as they do not, like these, get into the runs of water, but dabble or poke in the silt and sludge. They get the generic name *Limosa* from their searching the slime of the pools and streams, and they are sometimes called "ooze-suckers," though they of course do not actually suck the ooze and sludge, but merely search it with their bills for the mollusca, worms, and other small animals which it contains. Sight can be of no use to them, and thus they depend on the sentient properties of the bill, as an organ of feeling or touch.

They are birds which consume the surplus produce of places which are very peculiar, and not only widely apart from each other, but subject to great seasonal changes. Thus the godwits are all birds of passage, shifting from one region to another as the seasons alter the characters of those places in which they find their food. At one season of the year the frost drives them from the more northerly parts of their range,

and at another the drought drives them from the more southerly. They are not, however, so exclusively migrants in latitude as those birds which feed upon vegetables, or upon larvæ and other animals, which depend in a great measure upon the seasons of vegetation. Their food is in the sludge, and there are so many and such varied little animals there, that, if there be the requisite quantity of moisture, in countries which are perennially suited to their habits, they remain all the year without migrating; and such countries are generally about the middle of the temperate latitudes. They breed in the marshes, a considerable way inland, if the situation suits them; but in the winter they descend nearer to the seas, and may be met with in the oozy bays and estuaries, though not decidedly in the salt water. When inland they conceal themselves among the aquatic plants in which they nestle; and when they come to the sea, they are abroad only at those times when the state of the tide is favourable for their very peculiar mode of feeding. The mornings and evenings are the times at which they are most upon the alert; and then they may occasionally be seen running about with great velocity, and poking in the soft and moist earth for those little creatures upon which they feed. They are, however, better known by their cry, which is shrill and peculiar, and bears some resemblance to the bleating of goats. Godwits belong to that class which the epicures term "gut-birds;" as such they are highly prized; and when they make their appearance in the London markets they fetch a high price, partly on account of their real value and partly from their rarity. There are several species, and two at least are British, though these, on account of their variations in plumage with age or with season, have been described as four or more.

**THE BLACK-TAILED GODWIT (*L. melanura*)** is the species best known to British ornithologists, and it certainly still breeds in the fens, though in fewer numbers than formerly. At one time or another it has got a great variety of names, and has been called a snipe, a woodcock, a plover, and many other things which it certainly is not.

The chief cause of the confusion which there is in the names and descriptions of the bird, appears to be the changes of plumage to which it is subject; but there are some characters which remain constant in all those changes, and by them it may always be known. The chief, and they are sufficient for the purpose, are the bill and the tail. In the bill, the curvature upward is so very slight that it cannot be discerned by the naked eye, without the application of something straight to it, and it is probably on this account that this bird has sometimes been called a snipe. The point of its bill is, however, not nearly so much thickened as in the snipes, which shows at once that the godwit seeks its food in softer mud, and therefore is closer to the margins of the waters than the snipes. One sees a very beautiful gradation in these birds, the snipes are very near the water, the godwits are close upon it, and the avocets are in it altogether. In the tail the permanent character is the colour; black in the two-thirds next the point, and white in the basal third. If these characters are attended to, the bird cannot be mistaken, whatever may be the colours of the rest of its plumage.

In its summer plumage the head of the godwit is reddish brown, streaked longitudinally with dusky black. The lower neck behind, the back, and the

scapulars, are of a black colour, cross barred and more or less margined with brown. The wing coverts are brown, the lesser ones having white margins; the quills are dusky brownish black with white at their bases. A streak of a dull whitish colour passes over the eye, below this the cheeks, throat, fore neck, and breast, are pale reddish brown, and all the rest of the under part pure white; such is the black-tailed godwit in its nuptial attire. In winter, however, its colours change so much that we ought not perhaps to blame those who, before the habits of birds were so well known as they are now, called it by another name, and described it as a different species. In winter, the whole of the reddish brown on the fore part of the bird fades into pure white; the brown on the upper part becomes pale grey, and the black dusky brown; even the flying feathers of the wings become dusky or brownish, which is not the case in many of those birds which otherwise change their colour entirely with the seasons. Even the black in the tail fades considerably at this time; but it still maintains as much depth as to preserve the character of the bird. The black-tailed godwit is about seventeen inches in length, and three quarters of a pound in weight when in good condition, but the individuals vary in size and weight at different times of the year.

As noticed formerly of the genus, the black-tailed godwit is an exceedingly shy and hiding bird. It is all day in the tall herbage; and as it nestles and hides itself in the tufts and hummocks of the sludgy parts of the fens, it is very rarely seen in proportion to its numbers; and those numbers do not appear to be great, neither is the bird much distributed over the country. In north Holland it is by no means a rare bird, and it is probable that of those which appear in the fen districts of England during the winter the greater part come across from Holland; for, though this species is by no means a very discursive bird, or much given to migrate, the distance from Holland to Norfolk is not long for a flying creature, and the wind may often bring those to England which are shifting their grounds as the marshes of Holland begin to freeze, just in the same manner as that wind helps the birds of Siberia in an occasional visit to our shores. These birds breed inland in the fens, their nests are hidden, and the eggs, which are very rarely seen, are four in number. The young of the year have the plumage much more dingy and mottled than the old birds, so that they have occasionally been described as a distinct species. Indeed so long as colour was made a principal specific distinction among those long-billed fen birds, there was no determining how many there were; for summer and winter, young and old, and in some cases male and female, all had sufficient difference to mark them in this way. We shall offer some general remarks on these birds, and their localities and movements, in a general article LONGIROSTRES.

THE BAR-TAILED GODWIT (*Limosa rufa*) is the only other species which has been observed in England; and it is known only as a winter visitant. Even as such it is very capricious, appearing some years in considerable numbers, and in other years scarcely at all. It is generally said that this species comes most abundantly in those seasons when the other is rarest. This fact, which wants further confirmation before we can implicitly rely on it, might lead to something important in the distinction of the

two, respecting the causes why they migrate; because it would imply that a different kind of season drives each species from its continental haunts.

The bar-tailed godwit has its permanent characters in the same parts of the body as the black-tailed one. Its bill is considerably more curved, although even it has not a very great curvature, at least nothing compared to that of the avocet. The tail is throughout its length white in the ground colour, and regularly cross-barred with black. The tarsi are also shorter in proportion; and there are considerable differences in the tints of the plumage, although in this respect there is still a good deal of resemblance. In the summer plumage, the reddish brown on the head is more entire, and there is more reddish brown on the back. The summer tint of the fore neck and breast is also a more lively red; and there is no white on the bases of the quills. In winter the general plumage becomes greyish, and the red-brown on the breast fades to a greyish white. In this state, however, it is easily distinguished from the black-tailed species. The young of the year are entirely white on the under part, except the fore neck, which is mottled with greyish. The upper part is mottled with brown and greyish white, and the black bars on the tail are much smaller, and not nearly so well made out. In this state a random individual sometimes comes to our eastern shores about the middle of autumn. These are smaller in size than the mature ones, and have been described as the cinereous or ash-coloured godwit, of which Bewick gives a very faithful representation.

We have been thus particular in pointing out the distinctions between those two species of birds, and the various changes of plumage in each, not only for the purpose of so far correcting the pointed blunders which are in circulation respecting them, but because they are among the most curious of our fen birds; therefore information is desirable to those who have the opportunity of examining the fen districts personally, which, of course, are those on the spot, and familiar with fen travelling. To ordinary persons, how zealous soever they may be in matters of natural history, there is a sort of *taboo* upon the fens; for he who could set at perfect defiance the briars and brambles of a common, the heath of a mountain, or even the ocean surges themselves, would hesitate a little to advance on concealed ground, where the very next step might plunge him neck deep in sludge as black as Styx.

GREAT MARBLED GODWIT (*L. fedoa*). This is an American species; and, as Wilson's description of it is the best, we shall quote from it as much as we deem necessary for our purpose. "This bird," says Wilson, "is a transient visitant of our sea-coasts in spring and autumn, to and from its breeding place in the north. Our gunners call it the straight-billed curlew, and sometimes the red curlew. It is a shy, cautious, and watchful bird; yet so strongly are they attached to each other, that, on wounding one in a flock, the rest are immediately arrested in their flight, making so many circuits over the spot where it lies, fluttering and screaming, that the sportsman often makes great destruction among them. Like the curlew, they may also be enticed within shot, by imitating their call or whistle; but can seldom be approached without some manoeuvre. They are much less numerous than the short-billed curlews, with whom, however, they not unfrequently associate. They are

found among the salt marshes in May, and for some time in June, and also on their return, in October and November; at which last season they are usually fat, and in high esteem for the table. The female of this bird has been described by several writers as a distinct species from the male; the chief difference consists in the undulating bars of black with which the breast of the male is marked, and which are wanting in the female.

"The male of the great marbled godwit is nineteen inches long, and thirty-four inches in extent; the bill is nearly six inches in length, a little turned up towards the extremity, where it is black, the base is of a pale purplish flesh-colour; chin and upper part of the throat whitish; head and neck mottled with dusky brown and black, on a ferruginous ground; breast brown, with wavy lines of black; back and scapulars black, marbled with pale brown; rump and tail coverts of a very light brown, barred with dark brown; tail even, except the two middle feathers, which are a little the longest; wings pale, ferruginous, elegantly marbled with dark brown, the four first primaries black on the outer edge; whole lining and lower parts of the wings bright ferruginous; belly and vent light rust colour, with a tinge of lake. The female differs in wanting the bars of black on the breast. The bill does not acquire its full length before the third year." It is not very clearly ascertained whether there are any more distinct species than this one in North America. It is not, however, unlikely, because North America is very extensively adapted to the habits of such birds. The same mistake has been committed with regard to the above species, as in those of England. Either the young, the female, or the male in a different plumage from what it generally appears in, in the same locality, has been described as the marbled godwit. In all probability it is the young, for the young of all these birds have the plumage much more mottled and broken than the old ones.

Species have been mentioned as occurring in Siberia, and also in the east of Europe; but it is doubtful whether these are true godwits. They appear rather to be snipes; and the shades of distinction between snipes and godwits are, in some species of snipe, so fine, that casual observation of the one without having the other to compare with it, is very apt to occasion mistakes. One who goes to a distant country requires to be a most experienced ornithologist before venturing to decide positively on minute specific differences, especially in such birds as those now under consideration. The snipes are puzzles in themselves, and the difference between snipes and godwits is equally puzzling; and in some cases it must, in part at least, be decided by locality. Indeed the only way in which one can get a clear and satisfactory view of the distinctions between those genera which inhabit nearly, but not altogether, the same grounds, is to take the differences of ground along with the differences of inhabitant. Now the snipes are very generally distributed, at least, over large tracts of the land, while the godwits are few in number, and their localities far more limited. The different structure of the bill is the chief organic distinction which leads us to this. The bill of the snipe is a boring bill, and from its straightness, and its consolidation at the tip, capable of penetrating mud of some consistency. The bill of the godwit, on the other hand, is a scooping bill to a very slight

degree, and not fitted for such boring as the bill of the snipe. If we carry the comparison a little farther from the godwit to the avocet, we find in that bird the scooping bill in its utmost perfection; and the avocet may accordingly be considered as the very last land bird which feeds in the waters; because beyond what the avocet scoops standing in the rivers, there remains nothing more to be done till the bird actually floats and dabbles, as is the case with the ducks.

In these birds we have the land birds fining off to a vanishing line, at which they gradually glide into the water birds; and it is not a little curious that in proportion as the shade in distinction between land and water becomes finer, the birds become fewer in species and numbers, and more limited in their geographical distribution. Snipes are abundant; godwits are far less so; and avocets are the least so of any, so that the number of species and of individuals is in exact proportion to the extent of pasture.

This is a beautiful instance of harmony and design in creation; and as we meet with it at a point where we are prepared for doing so, it strikes us the more forcibly. This, however, is the rational and instructive, as well as the delightful way of studying natural history; and really nobody but a poulterer has any business to know any thing about birds, unless he knows as much about the places which those birds inhabit.

We may mention here, because it will save room in another place, that there is one species of bird which is not uncommon in the north of Europe, and which has been called the *lesser godwit*, and the *Jadrecka snipe*, which, though it is not, properly speaking, either a snipe or a godwit, was not unhappily named by Linnæus, *Scolopax limosa*, "the godwit snipe." The following is the description of this bird as given by Latham; and we believe it is correct in the details, though perhaps not entirely so in localities. "Length seventeen inches; weight nine ounces; bill near four inches long, dusky, the base yellowish; irides white; the head and neck are cinereous; cheeks and chin white; back brown; on the wings a line of white; vent and rump white; two middle tail feathers black; the others white at the ends, which increases on the outer feathers, so as the exterior ones are white for nearly the whole length; legs dusky. This bird inhabits Iceland, Greenland, and Sweden. Migrates in flocks in the south of Russia; seen about Lake Baikal; and is said also to have been met with in England." This bird, which has the feet partially webbed, is very justly considered by Cuvier as intermediate between the godwits and the avocets.

**GOLDEN ROD** is the *Solidago virgaurea* of Linnæus, one of a large genus of herbaceous plants, common in every botanical collection.

**GOMPHOCARPUS** (R. Brown). A curious flowering genus of flowers from the Cape, closely allied to the old genus *Asclepias*. It flowers and produces seed plentifully in greenhouses, and is thereby easily propagated, or it may be increased by cuttings in the usual manner.

**GOMPHOLOBIUM** (Smith). A genus of fine flowering plants from New Holland. It belongs to the tenth class of Linnæus, and to the natural order *Leguminosæ*. Generic character: calyx five-parted, parts nearly equal, broadly lanceolate; corolla standard, large, expanded, and emarginate; style incurved and deciduous; pod globular, and full of seeds. These plants grow best in very light sandy loam, re-

quire very moderate watering. Young cuttings root readily in sand, or they may be raised from seeds which ripen occasionally.

**GOMPHUS** (Leach). A genus of large dragon-flies (*LIBELLULIDÆ*), which see for the characters, having for its type the *Libellula vulgarissima*.

**GONEPTERYX** (Leach). A genus of butterflies, separated by Dr. Leach from the genus *COLIAS* (which see), chiefly on account of the angulated wings. The type is the brimstone butterfly of collectors, *Papilio rhamni* of Linnæus, a handsome species of a fine brimstone colour, found in most of the woods near London, and which makes its appearance very early in the spring.

**GONOLEPTES** (Kirby). A remarkable genus of arachnidous animals, belonging to the family *Phalangidæ*, having the hind legs very much thickened, elbowed and spined. The species are of a comparatively large size, and are for the most part natives of South America.

**GONOLOBUS** (Michaux). A genus of climbing perennials, natives of South and North America. The flowers are pentandrous, and, from the curious form of the parts, are arranged in the natural order *Asclepiadææ*. The plants are propagated by cuttings in the usual way.

**GOODENIA** (R. Brown). A genus of fine flowering herbs and under-shrubs, natives of New Holland. Class *Pentandria*, and natural order *Goodeniææ*. Generic character: calyx five-cleft; corolla tubular, and one or two-lipped, limb in five parts, with colourless margins; anthers distinct; stigma a simple indusium, somewhat ciliated; capsule two-celled, with parallel partitions; seeds flat. They are easily propagated by seeds which ripen plentifully, or by cuttings.

**GOODENOVIÆ**. A small natural order, containing five genera, and above twenty species. The genera are natives of the South sea islands; are herbs or under-shrubs, and are all rather pretty plants, and well worth cultivation.

**GOOD NIGHT**. An Indian hothouse-climber; is the *Argyreia* or silverweed of Loureiro, and the *Argyreia bona-nox* of Sweet; formerly the *Lettsomia bona-nox* of Roxburgh. Generic character: calyx of five conniving sepals; corolla cylindrically funnel-shaped; limb plaited, nearly five-lobed; stamens included, unequal; filaments joined to the tube, thick at the base; anthers erect, and arrow-shaped; style filiform; stigma double. Natural order *Convolutaceæ*.

**GOOSE** (*Anser*). A genus of web-footed birds, belonging to the flat-billed or *Lamellirostral* division, and the *Anatidææ*, or duck family. A slight notice of the relations in which the geese stand to the rest of the family, and also to some of the other orders which they approach, will be found in the article *ANSER*; and their general relations are noticed in the article *BIRD*. They are, however, too important, both in nature and in a state of domestication, to be passed over in the slight manner in which they are there noticed, and therefore we shall advert to a few of the more remarkable ones here.

Geese are very numerous, as well in species, or, at all events, in varieties, as in individuals. They are most abundant in the polar countries, and much more abundant in those regions of the northern hemisphere than of the southern. It is true that we know much less of the birds of the far south than of the far north; but the habits of geese are such as to

warrant us in concluding that they are by no means numerous in that part of the world. Geese are, with few exceptions, completely web-footed, and they all can swim. Swimming is not, however, their proper and peculiar, or, in general, even their chief motion. If the structure of a goose, and the way in which the legs support the body, are compared with those of a duck, especially one of the diving ducks, which range farther upon the waters, and are more constantly there than the common ducks, we shall perceive a very remarkable difference in the purposes for which they are best adapted. The bodies of such ducks are, as one would say, "boat-built;" that is, they are evidently formed for getting through the water rapidly at a small expense of effort; their legs, too, are placed far backward, so as to strike against the water, which follows in the wake, and this gives great advantage to the stroke, much more so than if it were given more in advance. Besides, they have the oblique motion, which throws the foot to a distance from the body, and partially turns it in such a way as that it can be brought forward with the least resistance. They are thus, strictly speaking, swimming birds; and though all of them have considerable power of wing, they are not less expert in the water than those birds which can fly comparatively little, although they are better at walking along the ground. The goose, again, is properly a walker, although the power of swimming is added, and in some of the species the two powers are nearly equal, and there may be some in which the swimming predominates.

Geese are also much more exclusively vegetable feeders than the rest of the family, at least with the exception of the swans; and the swans are much more aquatic in the feeding than the geese, for which habit they are well adapted by the greater length of their necks. Geese never dive, nor do they, in many instances, feed below the surface of the water, though they often feed, while swimming, on the seeds and succulent leaves of aquatic plants.

The generic characters are: the bill shorter than the head, higher than wide at the base, diminishing toward the tip, and thus having a slightly conical form. The teeth, in the margins and toward the tip of the bill, are conical, and the point of the upper mandible is generally furnished with a nail of harder consistence than the rest, and sometimes differently coloured. They are, generally speaking, polygamous, but there is no great external difference between the sexes. The old males are indeed rather larger than the females, but, before they reach maturity, the two sexes are very much alike both in size and colour, though this colour is, in many of the species, different from that of the mature ones.

The natural habitats of the geese are the damp meadows, and those tufted marshes which abound with plants, and they do not much frequent clear waters with pebbly shores. This species of pasture naturally points out why geese, in a state of nature, should be very migratory birds. In winter the land vegetation is covered with snow in every part of the northern regions, and this covering of snow generally extends to the shallow pools, and those tufts of vegetation which supply food for geese before the winter sets in. There is thus, therefore, nothing for them to eat on the landward part of the regions, in which they spend the breeding-time in the summer in the greatest number. The sea is, therefore, the only pasture

which is left open to such a bird as a goose in the high latitudes. In the extreme north the sea also is covered with ice, and with snow over that ice; and, even where this is not the case, geese are incapable of finding their food in the sea, even though clear of snow and ice to the high-water mark, which it seldom is, while the snow lies thick in the northern parts even of this country. Thus, in Scotland, though vast flights of geese pass over the country in winter, they never alight in the northern bays and estuaries, or on those deep lakes which have snow down to the water's edge. They come gradually southward, dispersing themselves over such of the inland pools and marshes as are not frozen, and as far to the southward, as long-continued frost and snow follow them, they move on; so that, in the course of a very severe winter, wild geese, of some description or other, range over almost the entire surface of the British islands. Their flight is high; and, though they do not alight except at such places as afford a prospect of food, yet there is no doubt that, from their situation at the top of the sky, they scan the whole horizon in their passage. It is doubtful whether any of them cross such mountains as the most lofty and broad-based of the Grampians, though they do make their way from the northern glens to the southern ones. Indeed, those marshy ponds, which are usually found about the parting of the water where two glens meet, are the places of favourite resort, more especially in the earlier part of the migration. The mode of flight is peculiar, but it can be better explained afterwards, when we are noticing those species most common in this country; but an attentive perusal of what we have said will easily show the reader why the geese necessarily leave their northern pastures during the winter, and also that, during this migration, they preserve, as nearly as they can, the same kind of feeding-grounds along its whole extent. It will also be seen, that those feeding-grounds are not frequented by any other race of migrant birds which the rigour of winter drives from the north, and hence one important use of geese in the economy of nature may be learned.

But there is another branch of the subject which is equally deserving of investigation, and that is, why, when they have escaped from the rigour of the northern winter, they return again? It has sometimes been satirically said, that "*A Scotchman is no goose*, for, when he migrates from the north, he seldom migrates back again;" and though this is only a little bit of pleasantry, there is more knowledge of natural history, to which it may be made a sort of artificial memory, than one would at first sight be apt to suppose. The Scotchman does not migrate northward, because he finds the southern pasture perennial, and, by parity of reasoning, the goose migrates northward, because to it the southern pasture is merely seasonal, and not perennial; and while barrenness sets in in the south, plenty begins to return in the north; and thus the geese are as true to their feeding instinct, or rather, as much impelled by the want of food in their voyage northward as in their voyage southward.

There again we may see, that how well soever the peculiar circumstances of the northern summer—the plentiful supply of food, and the long day, may assist those birds which migrate northward in summer, in the rearing of their brood, by enabling them to procure more provisions than they could possibly do in the south; yet it shows that the fact of migrating is

not, as nas sometimes been supposed, a consequence of any instinct, or propensity, arising out of the disposition to breed. This is a very important point to be established, because the migration of birds appears a very mysterious subject; and as the tendency of the unreflecting part of mankind is to solve all mysteries by their own mode of procedure, that is by forethought, purpose and plan on the part of the creature, this is a very dangerous ground, inasmuch as it makes those animals rational, by placing them not only on a level with man, but considerably higher; and thus virtually destroying the foundations both of religion and of moral obligation,—a consequence which many of those who have been the warmest advocates of the doctrine, would be the last to countenance by open means, however powerfully their unwise and unguarded assertions may indirectly promote it. From what has been said in the case of the geese, it is perfectly evident that their impulse, both southward and northward, is the momentary, and merely animal one of the desire of food, and the impossibility or difficulty in finding it; and that when a goose makes a spring journey from Lands' End to Labrador, its speculation does not at any one time extend a moment into the future.

The circumstances of the southern and northern countries, as contrasted with each other, are of themselves sufficient to show that famine follows, or forces a goose northward to plenty in the summer, as well as southward to plenty in the winter. We take the argument in this article Goose, instead of in any other part of this work; because the goose is a very generally distributed bird; because its migrations when in a state of nature are very decided; and because those seasonal changes, in consequence of which it must migrate or perish, are more general, and certainly more imperious than in the case of any other bird.

As the congealing influence of cold forces these birds from the north, so the drying influence of heat forces them from the south. Early in the summer, when the east winds continue cold and dry for a succession of weeks, the pools disappear, and the vegetation on the upland places is retarded. This state of things continues gradually northwards as the year advances; and a different state of things gradually mingles with it, and becomes a maximum in respect of it, after a certain limit is passed, till, when we come to the extreme north, this new state of things entirely predominates over the other.

We use the word "summer" upon this occasion, as a general name for all that part of the year during which the productive power of the earth is on the increase; and according to this mode of division, all the remaining part of the year is winter. There are many cases in which this is a far more convenient mode of viewing the differences of the year, than the division of it into four seasons. Everywhere, at least without the tropics, there is a summer and a winter; but spring and autumn differ greatly in the different latitudes of the range. In the extreme south of it, spring and autumn may be considered of longer duration than summer and winter, while in the extreme north, the duration of both of these seasons is not only very much shortened, but in some cases nearly, if not altogether, obliterated. There are instances even in the north of Scotland, in which the wild plants come into bloom within a week or two after the melting of the snow, and other instances in which winter comes in

so rapidly, that the corn in the ear, before it has yet come to maturity, is buried under the snow. In consequence of this we must look at the extremes as being the points that turn the two migrations of the birds, and the mean latitudes as being a mere passage or thoroughfare. Now at the times when in such a country as England, the pools are dry, and the grassy surface is burnt up, the snows of the northern surfaces are melted. But the melting of the northern snows, especially on surfaces that are comparatively flat, is a very different operation from the watering of the ground by rain. In hilly districts, there are very frequently heavy falls of rain accompanying the break of the storm; because the great differences of level, and consequently of pressure as well as temperature, occasion varied motions and clashings of different strata of the air. On the northern flats, however, the case is different. The snows simply melt, and melt gradually; and the water stagnates, and stagnates upon surfaces which have been warm by the snow, while the air is comparatively cloudless, and the sun heats strongly. This state of things is exceedingly favourable to vegetation; and such a powerful growth is soon produced as preserves this humidity for the greater part of the summer; and thus geese find abundance of food in those northern wilds to which they resort as their breeding quarters.

In tropical climates the causes and also the directions of those birds are different, because they follow the periodical rains; but still the original inducement to migrate with the seasons is substantially the same in the one part of the country as in the other. It is food which the birds follow after in those regions as well as in the others; though that which drives them in both directions in the tropical countries is drought, and not cold.

We have a proof of the most important fact above stated, namely, that the want of food is the grand cause of migration in those geese which are domesticated in our farm yards, and on our commons. There is no question that all the original varieties of tame geese are from the common wild goose, though, since foreign races were imported, some diversity has been produced by crossing; and as geese, like all animals in a state of domestication, are subject to very considerable variations in size and colour, there are differences between the domestic geese of different districts, but still these are all the same in habit; and unless when they occasionally join the wild ones, which they do only in those remote parts of the country where wild ones are numerous, and human inhabitants few, they show no disposition to migrate, provided they are supplied with food; and then, if the dry common happens to be burnt up, their migration is only to the next humid meadow, where they find a sufficient supply of grass. We shall now briefly notice the principal species or varieties.

**THE COMMON WILD GOOSE, or GREY LAG GOOSE** (*A. palustris*). This is generally understood to be the parent stock of all the domestic species of Europe; and according to the accounts, it is now much less plentiful in England, even during the winter, than it was formerly. This is no doubt, in a great part, owing to the drainage of the fens, the increase of cultivation, and the greater breadth of land which has been covered with artificial plantations of trees; for the wild goose loves humidity, but shuns alike the corn fields and the woods. In some parts of the north of Scotland this goose still rears its young; but it is

doubtful whether there are any absolutely wild in the fens of England: though as geese are reared in much greater numbers, and more in a state of nature there than they are at the farmyards, and on the commons in other districts, they no doubt approach more nearly to the wild state.

The size varies a good deal; but the average length is fully two feet and a half, or even more; the extent of the wings about five feet; and the weight about ten pounds. This last circumstance, however, differs a good deal with the season. When the birds first make their appearance, they are very much exhausted, and their flesh is so lean and tough, that it is by no means desirable. There are various reasons why this should be the case. The length and fatigue of the passage, for their excursion is at least five hundred miles, and in many cases more, without any food by the way, is of course one cause; and another is to be sought in the very circumstance of their being driven from their northern haunts by their want of food. They do not of course move till they feel the pinch of hunger (for no animal does this), and thus they begin their journey in an exhausted state. Such of them as remain in the southerly places till the spring, are, however, in much finer condition; and though they are never so fat, the flavour of their flesh is superior to that of tame geese, and more nearly resembles game; and when they have been well fed, and not fatigued by laborious flights, they are tender as well as of good flavour. The colours of the common wild goose usually are:—the legs and bill flesh colour, with the nail on the upper mandible and the claws dull white. The eyes are grey, as also are the head, neck, and principal portion of the body. The coverts of the wings, and also the quills, have white edges, and the tips of the latter are black. The secondary quills are more or less black, and the tail is of a dusky colour, bordered with white on the edges and at the point. The breast and the belly are white with grey mottlings.

This species of goose is not so well winged in proportion to its weight as the smaller ones which visit the British Islands; and hence it is probably a more southerly bird in all its migrations, though it has been ascertained that some of these others still breed in the wild and remote parts of the north of Scotland. The flights of those birds, more especially on their southern migrations, and toward the middle of the latitudes over which they migrate, are by no means uninteresting. They fly in flocks containing from about fifty to a hundred individuals, pursue their flight at a very considerable elevation, and rarely, if ever, alight to rest during the day, unless in places where there is a considerable supply of food. Their peculiar cry may often be heard during the day, when they themselves are either entirely out of sight, or so elevated as to appear like specks on the sky; but when they alight they are comparatively silent, and as they feed chiefly during the night, contrary to the habit of geese when resident, and in the tame state, they are not often seen in proportion to their numbers. There is a considerable difference in their mode of disposing themselves when they alight merely for rest, which they do at certain wayfaring places; and when they alight for wintering or for a more prolonged stay. In the latter case they observe no particular order, but spread themselves over the pasture, whereas, in the former, they always alight in line, and have a watchman or commander, a little

detached from the rest. After they have rested for two or three hours, this one utters the same signal cry which is given out whenever a single cry is heard as they fly along, and as soon as this is given they are all on the wing, and in the order of their aerial march.

Their flight is conducted with great regularity, for they always proceed either in a line a-breast, or in two lines, joining in an angle at the middle. They take the lead in this order by turns generally, the foremost falling back in the rear, when tired with cleaving the air, and the next in succession occupying its place. They are seldom within reach of a fowling-piece in these lofty flights; and even when they move in a lower track, they file so equally, that one discharge rarely kills more than a single bird. Their principal food consists of aquatic vegetables, and most sorts of grain. They breed in heaths, or in plains and marshes, as formerly in the fenny districts of England, and in various other countries, the female nestling on tufts of cut rushes, or dry herbage, and usually laying from five to nine eggs, and very rarely so many as twelve or fourteen. They are of a dirty greenish colour, and are hatched in about four weeks.

The young ones are taken in considerable numbers some years, and are then very easily tamed. The old birds, however, are extremely shy, and possessing the senses of hearing and vision in a pre-eminent degree, frequently contrive to elude the approaches of their pursuers. They often during the day take up their abode in the fields of young corn, which they damage to a very considerable extent; but they remain there during the day only, and when night sets in, they invariably take to the water, where they are secure from the invasion of the fox, an animal which has long been proverbial as the destroyer of geese; and though the usual time for preying to the fox is the night or in the morning, he is so fond of geese as that he will sometimes steal upon them even at mid-day.

Many writers on the economy of these animals have stated that the species, in a wild state, is generally diffused over the world; but it is probable that in this there is a good deal of exaggeration; and it is not unlikely that even in the northern hemisphere this has been confounded with others, in like manner as those geese which are subject to differences at different ages and in different individuals have unnaturally been multiplied into different species.

This, which, as we have said, is understood to be the parent stock of most of our domestic varieties, has been so long in a state of domestication, that it reaches beyond the earliest records of history; and though, by some means or other, the goose has got credit for being emblematical of folly, there are some instances recorded of singular services performed by it to the human race. Geese are very watchful birds; and when any thing strange appears, they set up a loud gabbling. It is in this way that the geese of the Roman capitol are recorded as having saved Rome from being captured by the Gauls, and thus they were long respected by that very superstitious people.

When domesticated, highly fed, and left perfectly at ease, geese grow to much larger size than they ever attain in a state of nature. Various arts, and often very cruel ones, have been, and are still, resorted to, for the purpose of fattening them for the table, and especially for enlarging their livers, which, when thus unnaturally enlarged, and consequently diseased, are much prized by a peculiar class of epi-

cures, although it is impossible that any part of animals which are treated in this manner can be wholesome. One mode of managing them is to nail the webs of their feet to a board on the floor near a strong fire, to sew up the vent, and forcibly to cram them with rich food, until they are at the point of death by suffocation; by this means the liver grows to an enormous size, and the goose itself increases in weight to twenty pounds and upwards. The fat of geese principally accumulates externally; and, generally speaking, it is difficult of digestion, and therefore unwholesome. In upper Languedoc, towards the Cevennes mountains, in France, there is said to be a breed which accumulates a great lump of fat on the lower part of the belly, which touches the ground when they walk. In other places there have been breeds that have showed considerable departures from the type of the wild goose, not only in colour, but in size and other particulars, which are understood to be less subject to those casual changes. It is mentioned that, a good many years ago, one family near Highworth, in the county of Wilts, were in possession of a breed of geese, which they nursed and fattened in such a manner, that they attained to a very extraordinary, and almost incredible size, insomuch that some of them would weigh from twenty even to thirty pounds. The owners could scarcely be induced, on any consideration, to part with an egg of this breed; and they sold the yearly produce of the flock to a few opulent families in the neighbourhood, at the rate of a shilling the pound. As an important department of the poultry establishment, the goose, we need hardly observe, is cultivated in almost every civilised quarter of the world, and, when under proper management, forms a profitable article of the farmers' produce, its quills, down, flesh, and even dung, being all turned to account. In this island these birds are nowhere kept in greater quantities than in the fens of Lincolnshire, several persons there having as many as a thousand breeders. They are stripped once a year for their quills, and no fewer than five times for the feathers. The first plucking for both commences about Lady-day, and the other four are between that and Michaelmas. It is alleged that, in general, the birds do not materially suffer from these operations, except cold weather happens to set in, when numbers of them die. The old ones submit quietly to be plucked, but the young ones are very noisy and unruly. These geese breed, in general, only once a year, but if well kept, sometimes twice. Each has a space allotted to it, in rows of wicker pens, placed one above another, during their sitting, and the *gozzard* (*gooseherd*) who drives them to water twice a day, and brings them back to their habitations, is said to place every bird in its own nest. The numbers of geese that are driven from the distant counties to London for sale are scarcely credible; for a single drove frequently consists of two or three thousand. In ancient times they appear to have been conducted much in the same manner from the interior of Gaul to Rome. The drivers are provided with long sticks, having a piece of red rag fastened to the end of them as a lash, and a hook is fastened at the other. With the former, of which the geese seem much afraid, they are excited forward, and with the latter, such as attempt to stray are caught by the neck and kept in order. Such as are lame are placed in a hospital cart, which usually follows each large drove. Their progress is at the rate of about eight

or nine miles a day, reckoning from three in the morning till nine at night. Those which become fatigued are fed with oats, and the rest with barley. However simple or awkward the goose may appear, it is by no means destitute of either sagacity or affection; and some singular instances are recorded of its attachment to animals of another class, and even to persons. The young, or *green geese*, as they are called, destined for the table, should be put into a place that is almost dark, and fed with ground malt, mixed with milk, when they will very soon, and at very little expense, be fit to be killed. Barley-meal may be mixed with water, should milk prove scarce, which they may constantly have by them to eat as they choose; and, in another part of the shed, some boiled oats and water, kept in a pan, to which they may resort, when inclined to change their food. This variety is agreeable to them, and causes them to thrive very speedily. *Michaelmas*, or *stubble geese*, should immediately after harvest be turned out on the wheat fields, where they pick up very fast; but when taken up to be fattened, they should be fed with ground malt, mixed with water, or boiled barley and water; and thus treated they grow fatter than would at first be imagined, and acquire a more delicate flavour than those in the London market. The old breeders may be plucked thrice a year, and at an interval of seven weeks, without inconvenience; but young ones, before they are subjected to this operation, must have attained to the age of thirteen or fourteen weeks, otherwise they will pine and lose their good qualities. It is scarcely necessary to add, that the particular nature of the food, and the care that is taken of the birds, materially contribute to the value of the feathers and the down. In those neighbourhoods where there is a good supply of water, they are not so subject as elsewhere to the annoyance of vermin; and they furnish feathers of a superior quality. In regard to down there is a certain stage of maturity, which may be easily discovered, as it is then easily detached, whereas, if removed too soon, it will not keep, and is liable to be attacked by insects and their larvæ. Again, the feathers ought never to be plucked long after the birds are dead, and, at the latest, before they are quite cold, else they will contract a bad smell, and get matted. Under proper management, and when unmolested by plucking, &c., the tame goose will live to a great age, even, it is alleged, to fourscore years, or perhaps a century. It is, however, seldom permitted to live out its natural life, being sold with the younger ones long before it approaches that period. The old ones are called *cagmags*, and are bought only by novices in market making; for from their toughness they are utterly unfit for the table. The tame goose lays from eight to twelve eggs, and sometimes more, which the careful housewife divides equally among her brood geese when they begin to sit. Those of her stock which lay a second time in the course of the summer, are seldom if ever permitted to have a second hatching; but the eggs are used for household purposes. In some countries the domestic geese require much less care and attendance than in this. Thus, among the villages of the Cossacks, on the Don, they leave their nomies in March or April, as soon as the ice breaks up, and the pairs joining, take flight in a body to the remote northern lakes, where they breed and constantly reside during the summer; but on the beginning of winter, the parent birds, with their multiplied

young progeny, all return and divide themselves every flock alighting at the door of the respective place to which it belongs. The accuracy with which they thus return to their several homes denotes more intellect than is generally ascribed to them. Another quality which they eminently possess is vigilance; for nothing can stir in the night but they are roused, and immediately commence cackling; and on the nearer approach of apprehended danger, they set up their shriller and more clamorous cries. Geese are capable of considerable attachment; and some of those attachments are of a peculiar nature, being shown not only to birds and to human beings, but to horses, cows, and other mammalia, and sometimes even to those whose habit it is to prey upon geese.

THE CANADA GOOSE (*A. Canadensis*). This species, which is also called the *cravat goose*, from its peculiar marking, is larger than the common goose of the eastern continent, though it is not much heavier, and rather a handsomer and better winged bird. Its length exceeds three feet, and the extent of its wings is more than five feet; the bill is two inches and a half long, of a dark colour, nearly black; the irides are dark hazel; the head and neck black, with a crescent-shaped white spot on the upper part of the eyes, which extends on each side of the head as high as the line of the eyes. This is the *cravat* from which the bird receives one of its names, and it is peculiar to this bird among the whole tribe of the geese. The lower part of the neck, anteriorly, is white; the back, the wing-coverts, and the upper part, generally greyish-brown, with white tips and margins to the feathers; the rump, the tail, and the primary quills, are black; the upper tail-coverts, and also the under ones on the rump, are white; the sides are pale brownish-ash; and the naked parts of the feet, and the webs of the toes, are blackish-ash. There is no difference in the colour of the two sexes, and very little in the size.

This species is the common wild goose of America, and it is as remarkable for its seasonal migrations there as the grey goose is in the eastern continent. In former times the flights of these geese were exceedingly numerous, and extended over the whole of the United States. But the Americans, perhaps copying the wild men of the woods, whom they have displaced, are much more disposed to shoot indiscriminately every wild animal, whether useful or injurious, and, if the former, whether it be or be not in season, than the people of Europe; and the Canadian goose has come in for a share of this work of extirpation.

No accounts have been given of the flight of those birds along the line of the Rocky Mountains, but they are observed on the west side of that ridge, and they are very plentiful to the eastward, their breeding places being in the extensive swamps to the northward of the American lakes, though they extend northward to the very shores of the polar sea. The swamps in this part of America afford, during the summer months, an asylum for marsh and aquatic birds of all descriptions, which it is difficult for man successfully to invade, and from which it is impossible entirely to extirpate their winged and summer-visiting inhabitants. In the summer months there are very extensive districts of this part of America peculiarly adapted as resting-places for aquatic birds, which are, at the same time, quite impracticable for human beings, the time when a passage can be made over them being when they are frozen; and the fur animals are the chief prize of the hunter at that season.

From this species being called the common wild goose in America, and the grey goose being the common wild goose of Europe, it is not very easy to say which of them is meant, when it is stated that the wild goose frequents Spitzbergen and the extreme north of Siberia. There is no doubt, however, that the present species ranges to the extreme north of the American continent. Indeed, if what Pennant records of them be true, their breeding places in America are farther north than any which are regularly inhabited by Europeans, or much frequented by the hunters during the summer. "The English at Hudson's Bay," says Pennant in the Arctic Zoology, "depend greatly on geese, and in favourable years kill three or four thousand, and barrel them up for use. They send out their servants, as well as Indians, to shoot these birds on their passage. It is in vain to pursue them. They therefore form a row of huts, made of boughs, at musket-shot distance from each other, and place them in a line across the vast marshes of the country. Each stand, or hovel, as they are called, is occupied by only a single person. These attend the flight of the birds, and, on their approach, mimic their cackle so well, that the geese will answer, and wheel, and come nearer the stand. The sportsman keeps motionless, and on his knees, with his gun cocked the whole time, and never fires till he has seen the eyes of the geese. He fires as they are going from him, then picks up another gun that lies by him, and discharges that. The geese that he has killed he sets upon sticks, as if alive, to decoy others. He also makes artificial birds for the same purpose. In a good day, for they fly in very uncertain and unequal numbers, a single Indian will kill two hundred. Notwithstanding that every species of goose has a different call, yet the Indians are admirable in their imitations of every one. The autumnal flight lasts from the middle of August to the middle of October. Those which are taken in this season, when the frosts begin, are preserved in their feathers, and left to be frozen for the fresh provisions of the winter stock. The feathers constitute an article of commerce, and are sent to England. The vernal flight of the geese lasts from the middle of April until the middle of May. Their first appearance coincides with the thawing of the swamps, when they are very lean. Their arrival from the south is impatiently attended; it is the harbinger of the spring, and the month named by the Indians the goose moon. They appear usually at their settlements about St. George's day, O.S., and fly northward, to nestle in security. They prefer islands to the continent, as farther from the haunts of man."

This species of goose shows equal disposition to be domesticated as the wild goose of Europe, if, indeed, not greater. It has accordingly been domesticated in many parts of America, and also in England, and various other parts of Europe. The following extract from Wilson will enable the reader to contrast the manners of the Canada goose with those of the wild goose of Europe:—"The flight of the wild geese," says he, "is heavy and laborious, generally in a straight line, or in two lines approximating to a point. In both cases the van is led by an old gander, who, every now and then, pipes his well-known *houk*, as if to ask how they come on; and the *houk* of 'all's well' is generally returned by some of the party. Their course is in a straight line, with the exception of the undulations of their flight. When

bewildered in foggy weather, they appear sometimes to be in great distress, flying about in an irregular manner, and for a considerable time, over the same quarter, making a great clamour. On these occasions, should they approach the earth, and alight, which they sometimes do, to rest and recollect themselves, the only hospitality they meet with is death and destruction from a whole neighbourhood, already in arms for their ruin. Wounded geese have, in numerous instances, been completely domesticated, and pair with the tame grey geese. The offspring are said to be larger than either, but the characteristic marks of the wild goose still predominate. The gunners on the sea-shore have long been in the practice of taming the wounded of both sexes, and have sometimes succeeded in getting them to pair and produce. The female always seeks out the most solitary place for her nest, not far from the water. On the approach of every spring, however, these birds discover symptoms of great uneasiness, frequently looking up into the air, and attempting to go off. Some, whose wings have been closely cut, have travelled on foot in a northern direction, and have been found at the distance of several miles from home. They hail every flock that passes overhead, and the salute is sure to be returned by the voyagers, who are only prevented from alighting among them by the presence and habits of man. The gunners take one or two of these domesticated geese with them to those parts of the marshes over which the wild ones are accustomed to fly, and, concealing themselves within gunshot, wait for a flight, which is no sooner perceived by the decoy-geese than they begin calling aloud until the whole flock approaches so near as to give them an opportunity of discharging two, and sometimes three loaded muskets among it, by which great havoc is made."

It is not very often that this species of goose makes its appearance in England in the wild state. When they do come, they come in considerable numbers, true to their gregarious character, and they come after very severe and long-continued storms, about the depth of winter. On their arrival they are very much exhausted, and easily taken; and cases are mentioned in which a whole flock has been taken alive and shared among the farmers, where they at once associated with the common domesticated geese, and showed no disposition to migrate, or even to escape.

THE SNOW GOOSE (*A. hyperborea*). This is another North American species, and, as the name imports, belongs to the far north of that country. The old and the young have been described as different birds, and in some instances they have been confounded with other geese which appear to have their native locality different. It is to be understood that the native locality of a migrant bird is that in which it nestles, and this one appears to abound nearly round the whole shores of the North Sea, or, at all events, from Hudson's Bay westward to Nova Zembla. It is here worthy of remark, that the longitude of Nova Zembla, which is sixty degrees, or four hours of time east of Greenwich, is the point of division between the two sections of polar migrant birds, just as the North Sea is the counter division, and the average of this, in the polar latitudes, is just about as many degrees of longitude west as the former point is east; so that one-third of the circumference belongs to what may be called the European section, and two-thirds to what may be called the Asiatic and the American.

In the middle latitudes, that is, about fifty degrees north, those sections meet in the Siberian flats, and of course often exchange even aquatic birds with each other; and when any of those birds which do not breed in the north of Europe, or in the islands to the westward, are driven to this country by stress of weather, it is highly probable that, though we are most familiar with them in America, as having possession of the north part of it, they do not come to us from America, but from Siberia.

This division of the birds in longitude upon the eastern continent is a point which deserves attention, as tending to assist in settling the localities of birds in two extensive districts, neither of which it is possible completely to explore. The reason why this is a point of division evidently is, that the mountains of Ural begin at the North Sea, and extend southward for a distance of nearly twelve hundred miles. Those mountains are lofty, their summits are rugged, their sides, or at least their skirts, are covered with pine forests; and thus they form a sort of barrier which no migrant bird, and more especially a goose, is likely to pass. We have no space for entering upon the investigation of this point in the geography of birds; but, as it has not been hitherto mentioned, we place it before our readers, in order that those who are fond of such subjects may turn their attention to it, as being one which is of special importance in any attempt to decide the locality of those rarer migrant birds which severe storms occasionally bring to our island.

We believe that all the heavy birds of long flight, which visit us in winter, and are not absolutely seabirds, at home and free denizens upon the broad waters, come from Siberia; and we do not think it difficult to show that, without an extraordinary effort, an effort, indeed, for which it is not easy to imagine an adequate physical cause, no such bird could, by possibility, reach England from the extreme north of America by coming south-eastward.

The reason of this is not only worthy of being stated, but it forms a very essential part of the history, in their state of nature, of all the geese which visit the British islands, and the species are not few, and the birds themselves are all valuable.

In the first place, and for a reason which will in part explain why our winter-visiting birds come from the north-east, and not the north-west, we get all our more violent winter storms from the same quarter.

The polar atmosphere, that is, about the latitude of the average north of both continents, is carried eastward by the earth at the rate of about three hundred miles in the hour, while in the middle latitudes of Europe it is carried about six hundred miles eastward at the same time. The consequence is, that, if we suppose a bird to fly south, with the air, of course, as the medium of its flight, it will always have less eastward motion than the air into which it comes; and we need not add, that this deficiency of eastward motion must tell as a westward motion upon the bird. Thus, even granting that there were no storm to drive it westward, a bird would move westward even in attempting to fly southward through the still air; and, as the very same difference of motion in the air is that which brings the storm from the north-east, the storm and the bird very naturally accompany each other. If we suppose a migrant bird to come from the north of America, we have this cause against the probability of its doing so, and to this we may

add the interruption occasioned by the Atlantic. We do not say positively that no birds (we are not speaking of sea birds) come to Europe from America, but the argument is against their doing so, and we are not aware of any physical cause in favour of it. But, to return to the bird under notice:—

The length of the snow goose is about two feet eight inches, and the extent of the wings about five feet: the bill is three inches in length, remarkably thick at the base, and rising high in the forehead, but becomes small and compressed at the extremity, where each mandible is furnished with a whitish rounding nail; the colour of the bill is a purplish carmine; the edges of the two mandibles separate from each other in a singular manner for their whole length, and this gibbosity is occupied by dentated rows resembling teeth, these and the parts adjoining being of a blackish colour; the whole plumage is of a snowy whiteness, with the exception, first, of the fore part of the head all round as far as the eyes, which is of a yellowish rust colour intermixed with white; and, secondly, the two exterior quill-feathers, which are black, shafted with white, and white at the roots; the coverts of these last, and also the bastard wing, are sometimes of a pale ash colour; the legs and feet of the same purplish carmine as the bill; iris dark hazel; the tail is rounded, and consists of sixteen feathers; that and the wings when shut, are nearly of a length. The bill is very singularly formed; the edges of the upper and lower gibbosities have each twenty indentations or strong teeth, on each side, the inside or concavity of the upper mandible has also seven lateral rows of strong projecting teeth: and the tongue, which is horny at the extremity, is armed on each side with thirteen long and sharp bony teeth, placed like those of a saw with their points directed backward: the tongue, turned up and viewed on its lower side, looks very much like a human finger with its nail. This conformation of the mandibles, exposing two rows of teeth, has probably given rise to the epithet laughing, bestowed on one of the varieties. This peculiar structure of the bill is attended with a peculiarity in the feeding of the birds. Their chief food is the roots of reeds and other strong aquatic plants; and they root these up in the marshes in the same way as hogs root up the meadows.

Brent Goose

THE BRENT GOOSE (*A. bernicla*) is a much smaller species than those hitherto described. It measures very little more than two feet in length, and about four and a half in the extent of the wings. Its general colour is brownish, with ash-coloured margins to the feathers. This extends over the upper part, the lower part of the neck and the breast, while the remainder of the under part is dappled with ash

colour and grey. The head and upper part of the neck are black, with the exception of a spot on each side of the neck immediately behind the throat, which is white, as are also the vent-feathers and the upper and under tail-coverts. The lower part of the back and the rump are also black. The tail-feathers, the quills, and also the feet, are dusky. The bill is dark horn colour, narrow and short, not exceeding an inch and a half. The eyes are light hazel, which form a very striking contrast with the black of the head. The most remarkable external character, however, is the white spot on the back of the neck, and next to that the uniformity of the upper plumage. In the females and young birds, the colours are not so well marked, and the neck spots are mottled with dusky.

This is a more discursive bird than the larger geese, being better winged in proportion to its weight, which is only about one half, seldom exceeding five pounds, while the three species previously enumerated may be said to average ten. The brent goose breeds chiefly in the very extreme north. It is found both in the eastern and western continent, and in all probability it ranges round the whole shores of the polar sea, the islands in which are its favourite resting places. It migrates southward in the winter, as far at least as the middle of France; and when the winters are peculiarly severe in the northern countries, brent geese often come in immense flocks, and are very destructive to the wheat fields. Buffon mentions that in 1740 and 1765, which were winters of great severity, brent geese attacked the corn fields in France in such multitudes that the whole inhabitants were raised *en masse*, and had no small labour in driving off and destroying these unwelcome strangers. In mild seasons these birds do not come so numerous as the common wild geese, neither are they so destructive; for, if the marshes are open, they prefer the roots of marsh plants to the *braird* of the wheat fields. We may mention here, as closely connected with the habits of this goose, that the chief attraction of geese to the polar marshes, is not the developed or green vegetation, which appears in those countries during their brief summer, it is the hibernating roots. In those countries the plants, marsh plants especially, work more by roots than by seeds; and though the leaves when they come up are generally coarse, the roots contain a vast accumulation of nutritious matter, far more than those of the larger marsh plants of more temperate countries. This is accumulated as a store for the action of the year, which, under the influence of a never-setting sun, is exceedingly rapid; and the moment that the snow melts and the ice breaks up, the geese are on the grounds, where, by partaking of this rich and abundant supply, they are soon in high condition, notwithstanding their long journey. They breed soon after their arrival, and their broods are out in time to nibble the young leaves of the plants.

**BERNACLE GOOSE** (*A. leucopsis*). This species of goose is of some celebrity in the annals of fabulous natural history, being the one which was anciently described as being bred not in the common way in which birds are, but growing out of the bernacle shell, which is a well-known pedunculated or stalked molluscous animal, having shells at the extremities of the stalks. Those animals are rooted, and they attach themselves to the bottoms of ships and to floating wood, as they are thereby carried from place to place. There is always a great deal of drift wood

in the North Sea; the storms, while they collect it in some places scatter it to others, so that the pieces float in all directions, and have very often bernacles on the under sides of them. In violent and long continued storms these bernacled logs of wood are frequently cast ashore; and the same circumstances often exhaust the bernacle geese, who do not come southward in very great numbers, unless the storm drives them. Their exhausted or dead bodies are often cast ashore along with the bernacled logs; and thus, at that time, when stories were believed, not in proportion as they were true, but in proportion as they were wonderful, the bernacle shells were set down as producing the geese which came ashore along with them. If this wonderful matter had been confined to the sea-shore, there might have been some plea for it; but several persons have pretended that there were eye-witnesses to the changing of bernacle shells into geese in the larger ponds in some of the middle counties of England, where neither bernacle shell nor bernacle goose is likely ever to be found. There is a satirical allusion to this in Butler's Hudibras; but as Butler never was single in his wit, if he could by any means double or treble it, he transferred the strange metamorphosis to the gannet or Solan, *quasi* Solon goose, as a hit at the foolish pretence at wisdom, which he was lashing.

"As bernacles turn Solan geese,  
I' the islands of the Orcaides."

The bernacle goose is still smaller than the brent goose, being less than two feet in length, and only a little more than four in the stretch of the wings; but it is not an unhandsome bird. From the tip to the corner of the gape, the bill is scarcely an inch and a half long, black, and crossed with a pale reddish streak on each side; a narrow black line passes from the bill to the eyes; the irides are brown; the head is small, and, as far as the crown, together with the cheeks and throat, white; the rest of the head and neck, to the breast and shoulders, is black. The upper part of the plumage is prettily marbled or burred with blue grey, black, and white; the feathers of the back are black, edged with white; those of the wing-coverts and scapulars blue grey, bordered with black near their margins, and edged with white; the quills black, edged a little way from the tips with blue grey; the tail-coverts and under parts white; the thighs are marked with dusky lines or spots, and are black near the knees; the tail is black, and five inches and a half long; the feet and legs are dusky, very thick and short, and have a stumpy appearance. This structure of the feet answers well, however, with some of the habits of the bird, as it is much more of a swimmer than most of the geese; and it does not migrate so far or so much inland. It is not uncommon during winter in the Orkney and Shetland islands, where it is called the *clack*, or "claik" goose. This word, which is merely a provincial orthoepy of the common word "clack," and alludes to the clacking gabble of those geese, has been represented to Baron Cuvier; and he has set it down in the *Règne Animal* as the Scotch name for a goose generally, which it is not. The mistake is a trifling one; but it deserves correction, as Cuvier's name must carry it far and wide, and preserve it long. It has not been ascertained that the bernacle goose breeds either in the islands or in any part of the north of Scotland, though it has been

ascertained that the brent goose does breed in Sutherland. There is, however, a difference of habit in the two: the brent goose frequents the fields and meadows, and is altogether more inland than this one.

**THE BEAN GOOSE** (*A. segetum*). This species is the wild goose of the more northerly parts of Britain; and it gets its name, not from any partiality that it has for beans, but from the nail on the tip of its bill bearing some slight resemblance to a small black horse bean. In its general characters it bears a very considerable resemblance to the grey lag, or common wild goose, and, on that account, some naturalists have confounded them. They are distinct species, however, and the bean goose does not come quite so far to the south as the other; though it occasionally makes its appearance in great numbers, which are very destructive to the fields of autumn-sown wheat, which they are very prone to. From the confusion that there has been of this with the other species, it is not very easy to reduce the accounts of them to any thing very precise; and so it may be that in all parts of the British islands this is the most abundant species. That it is in the north is certain; and it has been met with in the extreme south. It breeds in many of the more northerly of the Hebrides; and probably also in Orkney and Shetland, though there are no distinct accounts of the nests in those islands.

The bean goose varies considerably in size; but, generally speaking, it is about two inches shorter, and three or four inches less in extent of wing than the grey goose. The bill is also smaller in proportion, and more compressed towards the tip. It is of a pale flesh colour, or orange, with the exception of the nail, which is black, and which, as has been said, is the foundation of the trivial English name. This black nail is indeed the principal distinction; for, in other respects, excepting size, which is not a character, there is often a great resemblance between this and the other wild goose. Both mandibles of the bill are toothed rather more strongly than in the other. The eyes are hazel or brownish. The head and neck are ashy brown; the whole of the under part, as far back as the legs, is of the same colour, but paler, though on the thighs the colour is deeper. The forehead speckled with white, behind which the feathers are dusky brown. The back is ash-colour; the lower part of the belly, upper, and under tail-coverts white; the scapulars brown ash-colour, edged with white; the greater quill-feathers black; exterior webs grey; secondaries cinereous grey, margined with black on the outer webs. The coverts are grey, excepting the larger ones, which are grey, tipped with white. There appears to be some little variation in the plumage of these birds: in some the bill is of a dull brownish red; the upper part of the back, scapulars, and wing-coverts brown, dashed with cinereous, and tipped with white; greater quills plain dusky black; secondaries grey, tipped and margined with white. On the elbow of the wing there is a callous knob. The windpipe is enlarged about the middle, and its branchings into the lungs are short and inflated. These characters are quite sufficient to distinguish this species from all the others; and there is another character about them which is peculiar, that they are more impatient of restraint, and therefore not so easily tamed. They come to the British islands in the autumn, spread themselves over the country, frequenting the pools on the moors, but dispersing themselves during the day in the fields of

autumn wheat, on which they levy pretty heavy contributions. Their mode of flight is exactly similar to that of the grey geese; and in autumn and early winter numerous flights of them are observed *en chevron* over the middle parts of Scotland. In many districts they remain during the winter in the moorland pools, feeding in the day on the adjoining fields, and retiring to the water at night. In moonlight nights they are a tempting game to the rural sportsman; and as there is no game-law by which a wild goose is protected, they occasion those rustics to pass many a cold and anxious night. They are exceedingly vigilant, so that if there is not some cover between, they see the sportsmen before the sportsmen see them. Hence banks of turf are erected in favourable situations, behind which the shooters lie in wait with long Spanish-barrel guns; but it is doubtful whether the sport is, upon the whole, a profitable one. There is no poaching in the case, however, for poaching is a child of game-laws; and those who shoot bean geese in these places shoot them for themselves or for presents, and not for sale. When wounded in the wing only, they make a bold resistance, and bite almost as sharply as a toothed animal. Their feathers are also exceedingly close; and it is difficult to shoot them effectually, unless in the rear, or when their wings are elevated. Indeed, when obtained, the prize is one of glory rather than of gain to the rustic, for the flesh of the bean goose is more hard and tough, and in every way far inferior to that of the grey.

**THE WHITE-FRONTED GOOSE** (*A. albifrons*). There are some doubts whether this species, which comes to Britain in winter rather as an accidental straggler than as a regular visitant, may not be the young of the snow goose. At least this is the opinion of some of those who have written on the subject. When they come to the British islands they do not attack the corn fields, but confine themselves to the more humid parts of the marshes; and as the small flocks that do make their appearance are generally of one character, the probability is in favour of their being distinct, though they certainly have the same habit in feeding as the snow goose, and are the laughing geese of those who describe British birds.

The length is about two feet four inches, the extent of the wings about four feet and a half, and the weight about five pounds. The bill is thick at the base, of a yellowish red colour, with the nail white. A white patch is extended over the forehead from the base of the bill and corners of the mouth. The rest of the head, neck, and the upper parts of the plumage in some specimens are dark brown, and each feather is margined more or less with that colour; the primary and secondary quills are of the same, but much darker, and the wing-coverts are tinged with ash. The breast and belly are dirty white, barred with irregular patches of very dark brown, and tipped with lighter shades of the same colour. The tail is horny ash-coloured brown, and surrounded with white at the base; the legs yellow.

**THE RED-BREASTED GOOSE** (*A. ruficollis*). This is unquestionably an eastern species, and in the British islands it occurs only as a straggler. It is one of the most beautiful of the whole genus, both in its figure and in the markings of its plumage. It is above twenty inches in length, and about three feet ten inches in breadth. The bill is short, and of a brown colour; the nail is black; irides yellowish hazel; the cheeks and front dusky, speckled with

white; and there is a white spot occupying the space between the bill and the eyes with a black stripe beneath it, and is bounded above, on each side of the head, by a black line which falls down the hinder part of the neck towards the back; the chin, throat, and crown of the head are also black. Two stripes of white fall down from behind each eye, on the sides of the neck, and meet in the middle; the other parts of the neck and the upper part of the breast deep rusty red, and the latter terminated by two narrow bands of white and black. The back and wings are dusky; the greater coverts edged with grey; sides and lower part of the breast black; belly, upper and under tail-coverts white; legs dusky.

So far as is known, this species of goose belongs only to the eastern portion of those Arctic regions in which this genus of animals have their principal abode, at least we have no distinct account of their occurrence in America. The very few specimens which have hitherto been found in the British islands have been met with on the eastern side, and in the southern parts rather than in the northern. This is of itself sufficient evidence that the birds do not come to America, or from the polar regions of western Europe, but that they find their way across the low countries to the southward of the Baltic.

Red-Breasted Goose.

**THE EGYPTIAN GOOSE** (*A. Egyptica*). This also is a very beautiful species, resembling in its general form and characters the bernacle and brent geese, though its colours are more brilliant and the turn of the wing is furnished with a small spur. It has been long known in Egypt, and in ancient times it was much venerated in that country on account of the attachment which it has for its young. The ancient Egyptians style it the fox goose, but it is not easy to say for what reason. It has no character in common with any species of fox; and though foxes are particularly fond of all species of geese, it does not appear that they have any more partiality for this one than the rest. It is understood to be rather discursive, and on that account it is with difficulty retained in a domesticated state. It also suffers more from severe cold than any of those species which are natives of the north; and hence we may conclude that it does not in any of its migrations reach the cold latitudes. The length of this species is two feet two inches and five-eighths; breadth four feet four inches; weight six pounds. The bill is of a reddish colour, and, including a protuberance on the base of the upper mandible, is two inches in length; the nail black, nostrils dusky, irides pale yellow; a dark reddish chestnut patch surrounds the eyes and the base of the bill; the

crown of the head and the cheeks are of a dull dirty white, mixed with indistinct spots of rusty brown; the rest of the head, from the nape downwards over the whole neck, is of a dingy chestnut mixed and tipped with a lighter colour. There is a reddish chestnut patch on the breast, the upper part of which, with the shoulders, scapulars, and sides, are pale brownish yellow, beautifully marked or pencilled with dusky waved lines; the lower part is less distinctly marked, and appears of an ash grey colour; the belly white, as also are the wing-coverts; the greater ones are crossed or barred with a black line about half an inch from their tips. The secondary quills are clear reddish chestnut; those of the primaries which join them forming the speculum, which in varied lights are either of a resplendent green or purple; the rest of the first quills, the back, and tail are black; the under coverts of the latter pale chestnut; the legs are long, and, as well as the webs, are of a pale flesh-colour; nails black.

The information which we have with regard to the Egyptian goose in a state of wild nature, is not very clear or satisfactory; but the general assertion is that it ranges in Southern Africa, nearly as far as the Cape. If this is correct, it is an instance of a migratory goose performing all its movements in warm latitudes, and being driven both ways by heat and drought, and never by cold. The rains, in different parts of Africa, occur at different seasons, and as, though the rains are in general heavy when they do come, the drought is so severe and continued, as to burn up the vegetation and dry up the water, such aquatic birds as perform their migrations wholly within that continent, must of course move on y northwards and southwards.

**MADAGASCAR GOOSE** (*A. Madagascariensis*). This is one of the southern geese, and is a very beautiful bird. The upper parts are blackish with rich green reflections, and there is a large spot of bright sea green colour, surrounded with a black margin, upon each side of the neck; the forehead, the cheeks, the throat, and the under parts are pure white; the lower part of the neck and the flanks mottled with russet and brown; the upper mandible is yellowish; and the under one and also the feet are black. This difference of colour in the two mandibles, is a very decided external mark of distinction in this species from all the rest of the genus. The length of the male bird is nearly three feet and a half; the female is smaller, and the green spots on the neck are obscure or wholly wanting, while the upper part of the body is mottled with grey and brown, and the under part is pale greyish. The young resemble the female.

**JAVA GOOSE** (*A. Javanensis*). This is also a very handsome species, wholly tropical in its locality, though not confined to the island of Java, but occurring in the other islands of the Sunda group, and also in continental India; but, as is the case with many other animals which are common to these localities, its appearance varies in the different places. The upper part of this species is black, with very rich and brilliant reflections of green; the forehead and top of the head are blackish brown; the neck and the under part are white, lightly spotted with greyish; and there is a broad and well defined gorget of black on the lower part of the breast; the scapular feathers, the flanks and the rump, are finely rayed with black; the quills and tail-feathers are dusky, with a large black spot on the point of the former: the lower tail-coverts are white crossed by a band of black. This

is a small species, not exceeding a foot in length ; and it partakes a little of the characters of a duck.

**COROMANDEL GOOSE** (*A. Coromandeliana*). This is a still smaller species, not being above eleven inches in length, and it is possible that it may be only a climatal variety of the former. The upper part is blackish brown, with faint green reflections ; the base of the bill is surrounded with small white feathers ; the top of the head is dusky with green reflections ; and the back of the neck is spotted with the same colour on a sand-coloured ground ; the cheeks, the front of the neck, and the under parts are pure white ; the quills are dusky with white tips ; the bill is black, and the under sides of the toes dull yellow. Those parts which have green reflections in the male are dusky brown in the female.

**THE CHINESE GOOSE** (*A. Cygnoides*). This species is not called cygnoides, or swan-like, from any actual resemblance that it has to a swan in any other respect than in colour ; and that is not constant, for though it is sometimes entirely white, it is subject to great variety of colour. Though specimens have been brought from China, it is perhaps not very correctly styled the Chinese goose, inasmuch as it is found in many other parts of the south-eastern world, from China to the Cape of Good Hope, and as it is said, from New Zealand, though it does not appear to be met with in New Holland.

Several other species of southern geese are mentioned as being found on the Falkland Islands, on Terra del Fuego, and some other places of the southern lands ; there have also been others brought from South America ; but all these are too little known, we are too little acquainted with the migrations of birds in the southern hemisphere, and those migrations are in themselves on so small a scale compared with the migrations in the north, that all that could be said about those birds would be little else than a description of colours. There are, however, some other species which require a brief notice, because they deviate in some respects from the typical characters of the genus.

Those species which deviate from the proper character of the geese in many points, but which still essentially retain that character in others, may be divided into two sections : First, those which form a sort of intermediate link between the geese and the swans ; and, secondly, those which form a similar link between the geese and the wading birds, more especially the crane family, or perhaps the herons. We shall take them in the order now stated, without being very particular as to the correctness of the names, because though we are not quite satisfied with the existing ones, we do not feel ourselves called upon to contrive new ones, as our object is not to make systems but to give useful information.

**THE GAMBIA GOOSE** (*A. Gambensis*). This species is originally from the banks of the river Gambia, in Western Africa, and, besides the name which we have given it, it is called the spur-winged goose. It is about the size of the wild goose, but its legs are stronger and longer, and it is, altogether, more of a walking bird. Its bill and feet are of a reddish yellow colour, and the basal part of the upper mandible of the bill is furnished with a double tubercle ; the crown of the head and the neck are wood brown ; the ear-coverts and sides of the throat are white, mottled with brown ; the lower part of the neck, the sides of the breast, and all the upper part, are black in certain

lights, but in other lights the black disappears, and they show the most brilliant iridescent reflections of green and bronze. This rich play of colour is most conspicuous in the scapular feathers and in the quills next the body, but the margins of all the feathers on the upper part partake of the same. The turn of the wing, from the bastard-wing inward to the elbow joint, is white ; and on the wrist joint, at the origin of the bastard wing, or the turn of the wing, as it is usually called, there is a strong white spur of a horny texture, inclining upwards and inwards. All the under part of the bird is white. This seems to be a very discursive species ; for, though there is no doubt that Western Africa is its western locality, it has been found as an exceedingly rare straggler in the British islands, and a specimen was shot near St. Germans, in Cornwall, in the summer of 1821. The fact of finding a tropical bird, which is not usually a migrant in England, during the summer, is somewhat curious, though it accords with the general habit of birds which do not winter with us, but yet come regularly. Of the habits of this very handsome bird, in its native country, we know little ; neither do we know with precision to which of the species of geese that we know better we can connect it with the closest affinity. Probably the Egyptian goose is the nearest, and it also is an African species, remarkable for its beauty, and having a tubercle, though not a spur, on the turn of the wing. This one is usually considered as one of those which have a slight approximation to the swans, but in what this approximation consists, has not been clearly made out. Cuvier, however, places it in that division ; and we may remark, that Buffon, Latham, and some others, have confounded it with the Egyptian goose.

**THE SWAN GOOSE** (*A. Cygnoides*) is certainly intermediate in appearance between the swans and the geese ; and it is usually described as a swan, although, as Cuvier mentions, it domesticates, and even breeds with common geese in farm-yards, so that it lives much more upon the land than in the water, and has the habits of the geese, and not those of the swans. It is by no means a rare bird in Western Africa ; and it has been, to a considerable extent, domesticated in France. The following is the description of it :—This bird is rather more than three feet in length, and of a size between the swan and the common goose. It is distinguished from others of the goose tribe by its majestic walk and long neck, by having a large knob on the base of the upper mandible, and a skin (almost bare of feathers) hanging down like a pouch or a wattle under the throat ; a white line or fillet is extended from the corners of the mouth over the front brow ; the base of the bill is orange ; irides reddish brown ; a dark brown or black stripe runs down the hinder part of the neck from the head to the back ; the fore part of the neck and the breast are yellowish brown ; the back, and all the upper parts, brownish grey, edged with a lighter colour ; the sides, and the feathers which cover the thighs, are clouded with nearly the same colours as the back, and edged with white ; the belly white ; and the legs are of an orange-colour. These birds, it is said, were found only in Guinea ; they are now become pretty common in a wild, as well as a domesticated state, both in warm and cold climates. The female is of inferior size to the male ; the head, neck, and breast, are fawn-coloured, the upper part being somewhat paler ;

the back, wings, and tail, are dull brown, with pale edges; belly white. In other respects they are similar to the male, but they have a smaller knob over the bill. This very handsome and highly ornamental bird appears to be capable of enduring almost every variety of climate, and of breeding freely in them all; and we do not know, within the whole range of the poultry-yard, a finer ornament than the swan goose. It has been pretty generally introduced by those who attend to ornament as well as to use in their domestic birds; and we believe that it begins to be distributed in the wild state over some parts of Europe.

The birds which seem to connect the geese with the wading birds, but which still retain the principal characters of the goose genus, are southern birds, being found in South America, and still more strikingly marked in Australia. The length to which the present article has extended leaves room to do little else than to mention their names.

**THE ORINOCO GOOSE** (*A. jubatus*). This species appears to be pretty extensively distributed over South America, and though it has got the name of the Orinoco goose, we believe that it was first discovered in Brazil by Spix. It is of a variegated colour. The head, neck, chest, and vent-feathers, and also a mirror or spot in the wings resembling those in the cheeks, are white. The feathers on the occiput and back of the neck are produced and pointed, giving something the appearance of a mane. The upper part, and also the under part, are reddish; the wings and tail are of a black colour, with violet reflections; and the turn of the wing is furnished with a horny spur, something similar to that on the geese in the corresponding latitudes of Africa. The habits of this species are not very well known, though it is reported to partake as much of the character of a wading bird as of that of a swimming one.

**THE HALF-WEBBED GOOSE** (*A. semipalmatus*) is a native of New Holland. The upper parts are grey; the head, neck, and thighs, are blackish brown; there is a white collar round the neck, and the upper part of the rump is of the same colour. The length of the bird is about two feet nine. The webs extend only half the length of the toes, and thus it can walk much more easily than those which have the feet completely webbed. It also perches on trees, and in some of its habits approaches to the herons. We have not, however, a very full account of its character in its native locality.

**CEREOPSIS.** This bird, which has no very definite English name, the colonists of its native Australia not being the best of all nomenclators, ought, perhaps, to range in a separate genus; but still it has a good many characters in common with the geese, and more especially with the one last mentioned. It has the bill short, strong, and covered with a cere or naked skin, extended towards the point, which is arched and truncated. The lower mandible is sloped off at its extremity; the nostrils are very large, pierced in the middle of the bill, and entirely open. Four toes directed to the front palmed with notched membranes. The middle toe is shorter than the tarsus; and the fourth toe, which turns to the front, is furnished with a very large claw. The coverts of the wings are as long as the quills, of which the first is a little shorter than the other; there is a blunt spur on the turn of the wing; and the tail is broad, rounded at the point, and composed of sixteen feathers.

The cere and the naked skin, to the eyes, are yellowish; the principal colour of the plumage is greyish ash, darker on the upper part than on the under. The coverts of the wings are blackish. The quills are dull brown at their tips. The naked parts of the legs, which extend a considerable way above the tarsal joints, are yellowish orange; but the toes and claws are black.

The body of this bird is much shorter than that of the true geese, and is more of a triangular shape, or tapering from the anterior part of the sternum to the tail. The pectoral muscles are large; the windpipe is also large, but of uniform dimensions throughout, and resembling those of the herons and bitterns. The stomach is a true gizzard, indicating that the bird is principally a vegetable feeder. In some of the accounts the head of this bird is represented as being covered with naked skin, but such is not the fact; it has been brought to this country, and we believe that broods have been reared under the management of the Zoological Society of London. Still, however, the characters of the bird, or rather its habits in a state of nature, are but imperfectly understood; and we are still in want of much information respecting it.

There is one structural difference between this bird and the typical geese, in which the two species noticed immediately preceding also agree, and that is the different form of the keel of the sternum. In the geese that part of the bone is not low; but it is of uniform height throughout great part of its length, and nearly straight in its inferior outline; whereas in the species now mentioned, the great development of the sternum is forwards, as if the muscular power of the birds were more accumulated on the immediate organs of flight, and the lower outline is much more curved. In this respect the sternum, which in birds is a most characteristic part of the skeleton, approaches in shape to that of the long-flighted wading birds, the herons, storks, and others of that tribe; and as there is generally a correspondence between the organ and the formation, we may naturally suppose that these birds combine the habits of wading birds with those of geese; and thus they are enabled to summer and winter, without migration, in countries which are subject to great variations in respect of moisture and drought. Too little is known, however, of the habits and movements of the tropical and southern geese for enabling us to speak positively respecting them; and this article has already extended as far as the birds, important as they are, will bear.

**GOOSEBERRY,** is the well known *Ribes grossularia* of Linnæus. It is found wild in many places in Britain, and has been long cultivated in gardens for its very useful fruit, both green and mature. Of the *Grossularia* or aculeate *Ribes*, there are fifteen or sixteen known species, the fruits of all which are eatable, but the varieties of *R. uva-crispa*, are the most valued, and those in most general culture: the rough and smooth gooseberries (*syloestris* and *sativa*), considered the two chief varieties of *Ribes uva-crispa*, are often esteemed distinct species; the former being the *R. grossularia*, and the latter the *R. uva-crispa* of Linnæus. De Candolle, however, believes them to be specifically the same.

In Britain, gooseberries are much cultivated, especially in Lancashire, where from prizes being offered by the provincial Horticultural Societies, berries have been produced, each weighing an ounce or an ounce

and a half. Gooseberries, although grown, are not very common in the gardens either of Southern or Northern Europe : the heat of the summers in Spain and Italy being too great, and in Norway and Sweden the seasons are too rapid for the full development of the fruit. In England, as already observed, gooseberries are much esteemed, both as a dessert and kitchen fruit ; and the facility with which, when in an unripe state, they can be preserved throughout the year in bottles, from which the air has been excluded by boiling, renders them very servicable as a winter fruit. Gooseberries also, when preserved with sugar, make very good jams and jellies ; and, when fermented, an excellent wine is produced, which sparkles when the cork is drawn, and is known as English champagne.

The pleasant acidulous flavour of the gooseberry depends upon the presence of a malic acid blended with sugar ; and upon the varied proportions in which these two principles are developed, depends the fitness of the several varieties for dessert or kitchen use, for preserving or for making wine.

The cultivation of the gooseberry is exceedingly simple : young plants are raised from cuttings, taken from the trees in autumn, and planted then or at any time during winter. The cuttings are prepared by trimming off all the buds from the lower part, leaving only four or five at the top to form the future branches. The cuttings should be chosen from the strongest shoots produced from branches, not from the suckers from the root : the bottom and point is cut off, leaving the intermediate part fifteen or eighteen inches long ; six or seven inches of the bottom part is inserted into the ground, the like length forms the stem, and the branches issue from the top. Some pains are bestowed to give the branches a right direction to form the future tree. If they rise too erectly they are bent a little horizontally by hooks ; if too inclining, they are held up by forked sticks. The branches should be trained first outwards and then upwards, leaving the centre open and rather thin of branches. The summer shoots are produced along the branches, and which are annually pruned down to about an inch at the base. This is the chief culture gooseberry-trees require.

GOOSEFOOT is the *Chenopodium* of Linnæus and other botanists. They are found in all quarters of the globe, though mostly innocuous ; some of them have a most offensive scent and flavour, and are used medicinally as anthelmintics ; and many of them are used as spinach. The seeds of *C. quinoa*, or pertyrie, are used as food in tropical America.

GORRYTES (Latreille). A genus of hymenopterous insects, belonging to the section *Aculeata*, and sub-section *Fossiores*, and family *Crabronidae*, having three complete sub-marginal cells, of a squarish form, and of nearly equal size, the second of which receives two recurrent nerves ; the mandibles are internally unidentate, and the antennæ are somewhat thickened at the tips. These insects have much the appearance of small wasps, but they are solitary in their habits. Some of the species have the fore legs furnished with spines, and these are supposed to be the constructors of their own nests, whilst others are destitute of these appendages in the female sex ; and are, consequently, regarded by M. le Comte de Saint Fargeau as parasitic, and are accordingly considered by this author as belonging to distinct genera, the characters of which he has detailed in a valuable

monograph upon the group, published in the *Annals of the Entomological Society of France*.

GOSSYPIMUM (Linnæus). A beautiful and very useful genus of annual and perennial herbs and shrubs, chiefly natives of India. The flowers are monadelphous, and rank in the natural order, *Malvaceæ*. The great commercial importance of the cotton plant, or rather plants, for several of the genus yield cotton, makes its history interesting. In China the *G. religiosum* is chiefly cultivated, it yielding the yellow coloured cotton of which nankeen cloth is made. *G. herbaceum* is cultivated in many parts of the old world as well as in the new. *G. Barbadense* is a herbaceous annual, extensively cultivated in that and other West India islands. But the plant which affords the finest cotton, cultivated at the Isle of Bourbon, in the East Indies, and in South America, is probably what is called by Roxburgh, *G. obtusifolium*. This is a large, handsome evergreen shrub, much resembling in foliage and manner of growth the Judas tree of our gardens. The plants are put in about eight feet distances from each other, and in regular rows, and the ground is kept clean among them by the hoe. The plant begins to flower very early, or as soon as it is a foot or two high. The flowers are numerous, and followed by capsules, containing the seeds, wrapped in cotton. When the capsules burst the cotton and seeds are liberated, and then collected into baskets by children, who carry them to the warehouse to be, in the first place, freed from seeds, and afterwards packed in bales for sale. The seeds are separated from the cotton by children, by means of a small machine held on the lap. A crank handle, turned with one hand, moves two small metal cylinders, which revolve against each other so closely, that while the cotton, fed in by the other hand, passes through, the seeds are discharged behind.

It appears from parliamentary returns that the annual imports of cotton into this country are much above 227,000,000 lbs. These returns give some idea of the immense value of this plant in the manufacture of whose seed-down there is invested a capital in Great Britain alone of 56,000,000*l.*, giving direct employment to upwards of 830,000 of our population, and being manufactured into goods of the annual value of 36,000,000*l.*

GOURD is the name of the fruit of the *Cucurbita potira* of Linnæus. They are creeping plants, with gross stems, large leaves, and monstrous fruit. Their generic name is given from the circumstance that the shells are formed into various vessels for domestic use, such as bottles, basins, bowls, &c. Many of the species are cultivated as articles of food or drink, or medicine. Some of the bottle gourds (*Lagenaria*) grow to a very large size, forming flasks six feet long, by a foot and a half in circumference ; and, when quite young, are made into spoons. The Arabians call the plant *charrah*, and the poorer people often eat the fruit, boiled with vinegar, or fill the shell with rice and meal, and thus make it into a kind of pudding. Some of the bottle gourds have a bitter cathartic pulp, which may be used instead of colocynth ; but others, especially the cultivated varieties, have a sweet and esculent flesh. These latter are sometimes called sweet calabashes ; but they must not be confounded with the true calabashes, which are species of *Crescentia*.

GRACULA — Grackle. The French ornithologists call birds of this genus *martins*, and with them

there is no impropriety in the name, because they do not call those swallows martins, to which we give that name, and their *martinets* in the swallow family are our swifts, not our martins. In Britain, however, the name martin would be very improperly applied to the genus *Gracula*; because it would immediately suggest the notion of those familiar little birds which build their nuptial bowers with so much industry and ingenuity in the angles of our windows, whereas the genus which we are now very shortly to notice, are very different both in their appearance and their habits.

There are perhaps no birds of which the nomenclature is so confused as those of this genus, as scarcely two of those who have treated of them systematically, have agreed in applying the same name to them. In adopting *Gracula*, we follow Cuvier; but it is doubtful whether his generic characters will apply to all those birds which the continental writers include under the general name of martins. This part of the system is indeed not a little difficult, because the shades of characteristic distinction are very small and exceedingly numerous. In Cuvier's arrangement, the grackles belong to the dentirostral division of *Passeres*; and he arranges them near the choughs. They are all birds of omnivorous habits, though the principal food of very many of them consists of locusts and grasshoppers, in the destruction of the former of which they render important services to those countries in which they are found. The greater number are natives of the grand head quarters of the more splendid birds of omnivorous character; namely, the oriental Archipelago and the Oceanic isles; but some of them are found in the east and south-east of Asia, others probably in Africa, and certainly in Madagascar; and there is at least one species which comes periodically into eastern and central Europe, and in very rare instances makes a dash over into the British isles.

They resemble various other genera of the same part of the system. They have been classed in part at least with the thrushes, but they less resemble these than they do some others. If we consider them in respect of their food, they come perhaps nearest to the ant-eaters; and if we have reference to their general habits, they bear no inconsiderable resemblance to the starlings: like these last mentioned birds they are gregarious, appearing in numerous flocks; and it is this part of their habit which renders them so valuable in destroying the countless hosts of the locusts.

The generic characters are: the bill conical, and much lengthened, without any cere at the base, and with a slight notch at the tip of the upper mandible; both mandibles very much compressed, with sharp cutting edges, and a little arched, the nostrils oval at the base of the bill, and partly covered by a feathered membrane; the feet have four toes, the middle front one shorter than the tarsus, and united to the outer one at the base; the first quill of the wings merely rudimental, and the second and third the longest in the wing.

In their manners they are very familiar birds, little afraid of the immediate presence of human beings, and not much of the discharge of musketry. Indeed they will alight and feed in the fields, in the very middle of the people that are at work there, and pursue their useful labours as if they were fellow-workers with man. Their food is by no means confined to locusts, but extends to all the larger species of insects, which are so destructive to the produce of

the fields in the warmer regions of the world. The young are very easily tamed, and readily taught to repeat words; indeed when domesticated and kept in the farm yard, they imitate the cries not only of all the kinds of domestic poultry, but of sheep, goats, and almost of every other animal of which they hear the voice. It is probably in consequence of this familiarity in the manners of at least one of the species, that Temminck gave them the generic name of *pastor*, by which the only one occasionally visiting this country is generally known. The species are numerous; but our limits will admit only of mentioning one or two, which plan we must follow in the case of all the omnivorous birds of the same country which the grackles inhabit.

**COMMON GRACKLE (*G. tristis*).** How this bird came to be called *tristis*, "the sad," it is not easy to say; for in truth it is about as lively a bird as any of which we are acquainted. The usual length is about ten inches. The upper part marron brown; top of the head furnished with long black thread-shaped feathers; a triangular naked patch behind the eye; the principal quills black at the points and white at the bases; the tail-feathers brown, with the outer webs of the lateral ones white toward the extremities; the throat, neck, and upper part of the breast, deep grey, the rest of the under part dull white; and the bill and feet yellow. This species is very generally distributed, both through continental India and through the islands; and it is as serviceable in destroying those insects which attack vegetation above ground in those countries, as the common rook is for destroying the under-ground depredators of our fields; and where the inhabitants, inattentive to the uses of birds, have been inconsiderate enough to seek to exterminate the grackle, the same consequences have followed as when the same inconsideration in our own country has led to the destruction of the rook. When our rooks have been thus destroyed, the under ground swarms of coleopterous larvæ have cut off both corn and grass, at half an inch depth below the surface, so that in brief space hundreds of acres were perfectly bare; and just in the same manner the destruction of the grackles, and birds of their class, has been almost instantly followed by a desolating flood of locusts, which left behind them no green thing.

In the islands of Bourbon and Mauritius, these birds are held in the highest estimation. In former times, the produce of the fields was in the progress of being destroyed by locusts, the eggs of which, previously unknown in the island of Bourbon, were introduced with some plants from Madagascar, and they bred so rapidly, that the whole island was threatened with desolation. Poivre, the then governor, to whose science and patriotism the island owed so much, learning the great services which these birds performed in India, had a number of pairs introduced and distributed over the islands. They bred very fast, were diligent in their labours; and in a few years the locusts seemed extirpated. When this took place, the grackles began to dig and examine the newly sown fields; and the colonists, concluding that they did so for the purpose of eating the seeds, used every means to exterminate them, and soon succeeded. They, however, had reason speedily to repent, for no sooner were the grackles destroyed, than the ravages of the locusts began. Upon this a second importation took place, and in order to prevent a recurrence of their former folly, special laws were enacted for their

protection. They soon again cleared the island of locusts, and also the coffee plantations of those grubs which are so injurious to them. They next proceeded to attack the corn fields and orchards, and even to kill the young of pigeons and other domestic birds. This shows how rapidly they multiply; and the consequence was, the enactment of a sort of Malthusian law, for a positive check to prevent their numbers from exceeding the quantity of their legitimate food; and thus regulated, we believe, they did good without any admixture of evil.

**PAGODA GRACKLE** (*G. pagodarum*). This species is very plentiful in most parts of India, and has obtained its trivial name from perching on the temples. It is bluish-ash on the upper part, clouded with fawn colour toward the extremities of the wing-coverts. The top of the head and neck are furnished with long and silky feathers, of a black colour, with bronze reflections; but the shorter feathers on the head are buff colour variegated with white. The quills are black with bronze tips; and the tail-feathers bronze colour with white tips. The under part is buff with paler margins to the feathers. The under sides of the wings are white clouded with ash colour; and the base of the bill is black, but the greater part of the length of it, and also the feet, are yellow. The length is about eight inches.

**ROSY GRACKLE** (*G. roseus*). This species is much more discursive than any of the others; and as such it has been long known in the ornithology of Southern Europe. It used to be considered as a thrush, and was styled the rose-coloured thrush, by the earlier describers, while Selby, and some of the later ones, taking up the name given by Temminck, have called it the rose-coloured pastor. Its generic characters are, however, those of the grackles. It is about the size of the starling, that is, about eight inches long. The head, which is furnished with a large and handsome crest, is of a black colour, and so are the neck, the wings, and the tail; and all the rest is of a rosy tint, or rather something between peach blossom and salmon colour. The wing-coverts are inclining to brown with rich metallic reflections; and the feathers on the head, the crest, and the neck, are velvety in their texture, but with obscure reflections of purple and green. The female has the crest shorter, and the whole body inclining more to brownish grey. The young are brown mottled with grey; their legs are also brown, whereas the legs of the full grown birds are of a reddish colour. These birds come into Europe only in the summer; but they are exceedingly active and voracious, destroying vast numbers of the larvæ of the larger insects. They come along with the orioles, fly-catchers, and other birds which migrate from central Asia, as the ground there gets dried and parched by the ardours of the summer's sun. In general, those summer birds which migrate in longitude rather than in latitude, and come westward approaching the central heights of Europe in greater or smaller numbers, according to the character of the season, do not reach beyond those heights, excepting as stragglers; but they are all birds of powerful wing, and sometimes find their way to Britain. It is worthy of remark that, while our regular summer visitants, which come in numbers, have their localities, in which they are often very abundant, though quite unknown out of them, the stragglers, which come but rarely, come indefinitely to all parts of the islands, plainly showing that the birds are not, in any sense of

the word, "at home" with us, but are without the locality of their proper instincts, and therefore unable to select the places of their resort. These birds are handsome and beautiful; and when one happens to alight in the country, it is eagerly sought after as a prize of no ordinary value.

**WHITE-EARED GRACKLE** (*G. auricularis*). Upper parts rich bronze colour; head, neck, throat, upper part of the breast and coverts of the wings brilliant black; the top of the head furnished with long and silky feathers; a flesh-coloured naked space surrounding the eye; the ear-coverts white; the rump and under part pure white; the bill and feet yellow. This species is about eight inches long, and is found in some parts of India, but more abundantly in the oriental isles.

**CRESTED GRACKLE OF CHINA** (*G. cristatella*), has the whole plumage of a dull bluish black, with the exception of the tail-feathers and the quills, which have some white, the primary quills at their bases and the other quills at their tips. The head is furnished with a crest of long black feathers; and the bill and feet are yellow. This species is about eight inches and a half in length. It is found in the east of Asia and the isles.

**SILKY GRACKLE** (*G. sericeus*). This is a small species about seven inches in length. The upper parts are ash-coloured, with the coverts and quills black at the points and white at the bases. The head is yellowish white, almost yellow on the crown; the upper part of the neck yellow, and the under parts greyish white; the bill is purple red, and the feet reddish yellow. In the female the quills and coverts are brown, the top of the head black, and the forehead mottled with brown and white, which is also the colour of the flanks; the bill and feet are brown. In consequence of this, the two sexes have been sometimes described as different species.

There are various other species or varieties in the genus, but as they differ little in their habits, a description of them would be merely one of colour, and have no general interest.

**GRAINS OF PARADISE** is the *Anomum grana Paradisi* of Willdenow. These grains are stomachic and stimulant, but far less grateful as a spice than either cardamoms or ginger; they are often, however, substituted for the former, and have even been called the greater cardamom. The official cardamom is the fruit of the *Alpinia cardamomum*.

**GRAMINEÆ**. A truly natural order of plants, and one in which a very general resemblance obtains. According to Loudon's *Hortus Britannicus*, this order contains one hundred and fifty-eight genera, and one thousand and seventy-one species. For the facility of studying this extensive family of plants, it has been divided into sub-orders, sections, and divisions; but, notwithstanding this, long and intense study is required to enable a student to become an accurate practical graminæist.

It is hardly necessary to add, that the grasses are directly and indirectly the most valuable of all other tribes of plants for the use of man. To offer proofs of this would be to write histories of pastures, fodder, cattle, bread, corn, &c. &c., a knowledge of which is contemporaneous with our very being. All the principal and most useful species may be found described under their proper names.

**GRANATEÆ**. A small natural order, containing at present only one genus, *POMEGRANATE*, which see.

**GRAPE.** The fruit of the cultivated vine, so well known as to need no description. For the cultivation see article **VINE**.

**GRAPE HYACINTH** is the *Muscari* of Desfontaine, and the *Hyacinthus muscari* of Linnaeus, a common flower-bulb.

**GRAPSUS** (Lamarck). A genus of crustaceous animals belonging to the *Decapoda Brachyura*, and to the section *Quadrilateres*, of Latreille, having the shell or carapax nearly square, the legs flat, the eyes placed upon short foot-stalks at the anterior angles of the shell, and the antennae covered by the front of the latter. The abdomen is seven-jointed in both sexes. These crabs, of which many species are described, are, with a single exception, inhabitants of the seas of the East and West Indies. At Cayenne they are called *ragabeumba*, that is, soldiers. During the day they hide themselves under stones and other bodies in the sea; some, however, frequent rivers subject to the tide, but these generally are found upon the moist banks out of the water. It is said that they even climb up the trunks of trees, and seek refuge beneath the bark. They assemble in considerable numbers, and at the approach of danger retire to the water, striking their claws against each other with violence during their retreat. The only European species is the *Grapsus marmoratus* of Fabricius, which is found upon the coasts of France and England.

**GRASSHOPPER.** The ordinary name given to an extensive group of insects, forming portions of the great Linnaean genus, *GRYLLUS* (which see), and distinguished by the power which they possess of leaping to a considerable distance. In our article upon the *CERCOPIDÆ*, we have entered at some length into the various saltatorial powers possessed by insects, and have shown that in the greater number it is to the peculiar construction of the hind legs that they are indebted for such powers. In the insects now under consideration this is particularly the case, and as they are abundant in the summer and autumn months in every field and upon every bank, no insects are more easily discovered, owing to their perpetual chirping, nor are any more capable of showing the beautiful mechanism with which the motions of the insect world are provided than these. For rapid motion through the air with closed wings, it is proper that the body of an insect should present in its form as little resistance as possible; we find, therefore, the body of the grasshopper long and compressed. But it is the instruments by which this motion is imparted to the insect which now especially merit our attention. These are the hind legs, which are attached to the body, nearly in the centre, at the sides, by means of very powerful muscles, and which, instead of being short and formed for laying hold of objects, like the four anterior and intermediate legs, are longer than the entire body, and seem, when the insect is merely creeping about, to be dragged along without assisting in progression. The thigh is the strongest part of the legs, its basal portion being the thickest, and it gradually becomes more slender to the tip. Along its outer surface there are several ridges, which must evidently impart considerable strength to the limb, and the space between these ridges is likewise ornamented with oblique ridges, which give it a beautiful appearance. On looking at the limb from behind, a depressed space is observed along its entire length, margined on each side with strong spines, of which we shall subsequently notice

the use; the shank is more cylindric and slender than the thigh, smooth internally, but generally spined on its outer edge, and armed at its extremity with several very strong short spurs. This part of the limb is of the same length as the thigh, and is terminated by a short jointed tarsus, having two strong claws at the tip. We will now suppose the insect creeping upon the ground, and suddenly menaced by the approach of danger. For the avoidance of this danger it is necessary that a sudden spring should be made, and it is also necessary that for doing this the body should be thrown *upwards* in a greater or less angle, according to the distance to be gained. Now this is effected in a very peculiar and interesting manner; the thigh, in its ordinary position, is placed at an obtuse angle with the front part of the body, and the tarsus is placed at an obtuse angle with the shank; thus:

Great Green Grasshopper.

the tip of the shank or tibiae is then suddenly brought into contact with the base of the thigh, being retained in its position during the subsequent stroke by means of the spines upon the margins of the hinder edge of the thigh; but the tarsus is, during this operation, kept in an horizontal position; the obtuse angle, therefore, between it and the external extremity of the shank becomes, by degrees, a right angle and then an acute angle; the more the thigh is lowered the more acute being the angle between the tibia and tarsus; by this means the strong spurs at the extremity of the tibia are fully exposed and brought into action, being now, in fact, the support of the hind part of the body, and offering a very firm point upon the plane of position. A violent stroke is then made by the muscles of the hind thighs, the body is prevented from moving in a backward direction by the spurs of the tibia, and the body is accordingly propelled forwards and upwards, in proportion to the angle made by the tarsus and the tip of the tibia. But the grasshopper is often assisted in its motions by other organs, for no sooner is it in the air than it expands a pair of wings of a delicate gauzy texture, which had been previously folded up by means of many longitudinal wing-ribs, arranged like the ribs of a fan, beneath a pair of narrow wing-covers, often elegantly marked and coloured. We have been thus particular in explaining the mode by which the leaping of the grasshopper is effected, having only met with a short and insufficient explanation of it in the works of writers upon popular entomology.

We have said that the grasshopper is easy to be traced, from the chirping noise which it makes, but it is necessary to notice that it is only by one sex, the males, that this noise is produced. The same peculiarity also exists in the not less noisy *CICADÆ* (which see), although the apparatus by which the sound is pro-

duced is quite distinct. In the house and field cricket (see the article CRICKET), which are very nearly related to the grasshoppers, both forming, in fact, portions of the genus *Gryllus* of Linnæus, we have noticed the structure of the wing-covers, and in those species of grasshoppers, which have long and slender antennæ, the structure is very similar. De Geer, speaking of the great green *Gryllus viridissimus*, which is common near London, thus describes the structure as well as the mode in which the sound is produced:—"In that part of the right wing-cover of the male, which is folded horizontally over the trunk, there is a round plate, made of very fine transparent membrane, resembling a little mirror or piece of talc, of the tension of a drum. This membrane is surrounded by a strong and prominent nervure, and is concealed under the fold of the left wing-cover, which has also several prominent nervures answering to the margin of the membrane or ocellus. There is every reason to believe that the brisk movement with which the grasshopper rubs these nervures against each other, produces a vibration in the membrane augmenting the sound. The males in question sing continually in the hedges and trees during the months of July and August, especially towards sunset and part of the night. On approaching them they immediately cease their song." But the majority of English grasshoppers belong to a distinct section, having short and rather thick antennæ (and belonging to the same division as the locust), and in these the chirping is produced in a different manner, the thighs being rubbed alternately briskly against the closed wing-covers, which causes the regular breaks in the chirping; moreover, near the base of the hind legs, De Geer discovered a cavity partially covered by membrane, having a semi-circular aperture, which must evidently contribute in a considerable degree to produce and augment the sound.

The larvæ and pupæ states of these insects are very similar in form to that of the imago, the former being destitute of wings, and the pupæ having only rudimentary wings and wing-covers; hence, although in these states they are able to leap to as great a distance as when winged, they are incapable of chirping.

**GREBE** (*Podiceps*). A genus of *Palmipede*, or web-footed birds, belonging to Cuvier's family of divers, or short-winged birds, and placed as the first of that family in his arrangement. They are very peculiar birds in their structure and habits, and on that account they are highly interesting. They are, in one respect, the first of the aquatic birds; but they do not take up the connexion from the birds with sentient bills, whereof the avocet is the last. They take it up more from the herons, which find their prey by wading in the shallows, and seizing it in the free waters by means of a hard, firm, and sharp-pointed bill, which they can use with great precision.

The grebes seize the principal part of their food in a similar manner, only they have the power of committing themselves to the water, and seizing the prey when they are under the surface, and often at the depth of a good many feet. For this purpose they are admirably adapted, not only in the form and action of their organs of motion and prehension, but in the general form of their bodies, and in the texture of the feathers with which they are covered.

As the grebes take up the character where it is left off by the herons and those other birds which, wading but not swimming, capture their prey in the waters,

by a firm bill directed with very certain aim, so they transfer it to the sea divers properly so called, to those birds which subsist by following their prey under the surface in the free range of the oceanic waters.

The grebes are not, however, sea birds, though they can upon emergency make their way in salt water. They are inhabitants of the smaller lakes and ponds, especially those which are tangled with plants; and they are admirably fitted for making their way under water in such places. We must, however, mention the generic characters before we proceed farther with the general description.

The bill is of mean length, though generally longer than the head; it is straight, conical, and compressed or cylindrical in its section. The upper mandible is awl-shaped, and abruptly curved toward the point. The nostrils are lateral, and pierced in the middle of the length of the bill; oblong and open externally, but capable of being firmly closed internally by a membrane; and they have a communication the one with the other. The feet are articulated far backwards; the tarsi are very much compressed, and have membranous margins. There are four toes on each foot, three to the front and one to the rear; these toes are margined by broad and very peculiar membranes, which are, however, divided down nearly to the articulations; and it is on this account that the name of *Podiceps*, or "divided foot," is given to the genus. Of these toes the external one is the longest; and the fourth, or hind toe, is very compressed, bordered with membrane, articulated rather upon the inner side of the tarsus and touches with the point only when the foot of the bird is on the ground.

From this form of the feet, their distance laterally from each other, and the oblique motions of the joints both of the tibiae and the tarsi, the grebes are very clumsy and imperfect walkers. Their legs are articulated far behind the centre of gravity of the body, and thus they are unable to support it in a horizontal position, or any thing approaching to it. Those who think of no other use or office in a foot than that of walking upon the solid earth, would be apt to regard the foot of a grebe as the most unformed and awkward of all organs with which any animal could be furnished; but when we come to consider the use which the grebes make of this apparently awkward foot in the most important operations which they have to perform, we at once see that there is not in the whole range of the animal kingdom, wide and varied as it is, a finer instrument than the foot of the grebe. No human knowledge of the principles of mechanics could contrive such an instrument, and no human dexterity could form it, even though in possession of the plan. Oars and paddles, and other implements for the moving of boats and other craft through the waters, have been made of various forms and used with different degrees of effect in proportion to the power necessary for putting them in motion. Among them all, however, there is nothing which can be at all compared with the foot of the grebe, even if we leave its self-motion out of the question, and look upon it merely as a mechanical instrument. When the bird is under water (and it is rarely a surface swimmer) the foot is both oar and rudder. In giving the stroke which impels the body forward, the foot acts with the maximum of power in the direction which gives the power the maximum of effect. In

recovering the foot, that is in bringing it in advance through the water preparatory for a second stroke, the mechanism performs its office with equal perfection. When the full bent of the stroke is given, all the joints and membranes of the foot are at their greatest degree of tension, so that the foot strikes as if it were one expansion of solid matter, and the membranous border of the tarsus, together with the flat surface of the bone, assist in giving additional effect. As soon, however, as the stroke is given the whole foot relaxes, the tarsus turns with its thin edge to the front, and thus the foot is advanced and a new impulse given before the momentum of the body is visibly diminished. No feathering of an oar, even by a most expert rower, can at all compare with this recovering of the grebe's foot, though that manœuvre with the oar is a sort of humble imitation.

Grebes being chiefly inhabitants of those waters in which there is a good deal of vegetation, derive considerable advantage from the division of the foot, and they get additional power from the great length of the toe. The wings also keep 'stroke with the feet; and from their hollow shape and their firm texture, they may assist a little in the forward motion, yet the chief use of them is in directing the course of the bird, especially in ascent and descent; so that, thus furnished, the grebe has nearly the same command of itself in the water of the tangled pools as the divers have in the free water of the ocean.

The form, the covering, and indeed every thing connected with these birds, is a beautiful instance of the adaptation of structure to habit. No plumage resists the water better, or gets through it with less friction. Indeed the surface of the grebes is strongly repellant of water when they are alive; and though it is not easy to say in what this property of the feathers of birds which swim under water consists, the knowledge of it would be exceedingly useful in determining by what means, other than mere form and smoothness of surface, a vessel could be propelled through the water. The grebes afford a very convincing proof that this property is not obtained by the application to the feathers of an oil secreted by the glands on the rump of birds; but that, on the other hand, it must extend to the whole surface, to every feather, down even to the finest filaments of the webs. That it is something connected with life in the birds we are certain, because the dead feathers of those birds are soon wetted; and that it is not put on by any action of the bill, because it is just as perfect in those parts which the bird cannot reach with its bill as in those which it can reach.

There is another provision in the covering of the grebes which shows how well they are organised for bearing the temperature, as well as the other influence of the water. They are covered immediately under the skin with a considerable layer of fat; and that fat is of the same oily nature as the fat on the under sides of many swimming birds, and also on the bodies of whales. This fat gives a disagreeable rancid, or what is usually termed "a fishy flavour" to the flesh of grebes; but it is possible that, as is the case with many of the marine birds, this flavour might be, in great part at least, removed by burying for some time in fresh mould. This flavour appears to be a subject respecting which there are very general mistakes. The term "fishy" seems to be a misnomer, for it is not easy to see how feeding upon fish could communicate this flavour; because it is the flavour of a

substance which has undergone two complete changes, first, assimilation by the digestive process, and secondly, secretion by those tissues in which it is lodged. The way in which the particular nature of the food of animals modifies the qualities of their flesh is, however, a subject upon which much information is wanted before any definite conclusions are arrived at.

These birds are very miscellaneous feeders. They do catch fish, but their bills are not adapted for the capture of very large fishes; and they are known to feed on many other substances, such as spawn, water beetles, crustaceous and molluscous animals; and it has been alleged that they sometimes eat the more succulent roots of vegetables, though this is somewhat doubtful. They also swallow their own feathers, which they are careful to pull out the moment that they begin to decay; and as these feathers, mixed with the elytra of beetles, and other indigestible matters, are often found in pellets in their stomachs, it has been supposed that they "cast" these pellets in the same manner as owls and other birds of prey cast the indigestible "quids" of their food.

From their structure, grebes are very awkward upon the land; and therefore they come ashore as seldom as possible, and they are comparatively seldom on the wing. At those seasons when they have recourse to the sea, and the wind blows strongly in shore, they, like the other diving birds, have considerable labour in keeping themselves from being strangled, which they endeavour to do by swimming to windward. But though these are times of labour to them, they are also times of plenty; for the agitation of the water brings up a great quantity of those substances on which they feed, and so tosses about the smaller fishes that they also become an easy prey.

The nesting-places of grebes depend a good deal on the nature of their pastures; those which are more seaward, or inhabit waters destitute of vegetation, nestle in holes of the banks; whereas those which frequent the reedy and sedgy pools inland form their nests of vegetable substances, concealed in a tuft near the water's edge, and not unfrequently over its surface, if the standing vegetation is capable of supporting the nest. Those nests consist of a great bunch of vegetable matters, but, as the whole of these are the produce of the waters, they are much coarser than the nests of those birds which seek their materials on land. The nests of grebes are sometimes flooded, and the wind sometimes breaks them from their moorings, and drifts them to other places of the pools, without having sustained much injury. On these accounts there have been many mistakes respecting those nests. It has, for instance, been said, that they are purposely wetted, and that the fermentation produced by the humidity of such a mass of vegetable matter generates heat, which greatly assists in hatching the eggs. Now, this mistake, which is a very common one, involves two errors; one, in the physiology of warm-blooded animals, and a still greater one in the physiology of plants, or rather, perhaps, in the phenomena of decaying or decayed vegetable matter. So far as we know, there is no egg of a warm-blooded animal that can be quickened into life by any action of heat, if accompanied with moisture at the same time; and, on the other hand, the vegetables which grebes, and all other birds which use vegetables, construct their nests of, are past that state in which any moistening of them would produce either heat or fermentation.

There must be sap in vegetables, in order that either of those operations may take place, for a sapless vegetable merely dissolves mechanically in the water by maceration.

The other mistake is, that of supposing that grebes have forethought purpose, and thus build their nests so as to rise and fall with those waters which are subject to differences of level; that, in some circumstances, the heavy nest of a grebe, when placed so as to touch the surface of the water, may descend if the water is lower; and, as the weight is in the great volume, and not in the specific gravity of the dry leaves and stems, it is just as likely that such a nest will be raised by an elevation of the water; but that the grebe has any forethought purpose in this, is just as absurd as it would be to suppose that a grebe should go and examine whether a pond had a sluice to it or not, before beginning to build her nest; and not only this, but, before she could do what is said of her by purpose and contrivance, she would require a good deal of topographical knowledge; for the characters of the surrounding country, and that to a distance far exceeding any grebe's journey, very frequently determines whether the surface of a pool or lake shall be constant or variable.

We shall now give a short glance at some of the species of grebes; and, as they resemble each other very much in their habits, we shall make our remarks brief.

**RED NECKED GREBE (*Podiceps rubricollis*).** In the British islands this species is not very common, and we believe it has not been seen excepting in the winter. Still this circumstance does not warrant us in saying positively that it is a migrant, because grebes are not much on land at any time, and there is much more concealment for them upon the waters in summer than in winter. Besides, all our pool-breeding birds seek toward the cold and upland pools in the summer, because those pools are not so liable to be dried up as those in the warmer, more cultivated, and more thickly inhabited parts of the country. This is a species of the same instinct which brings the warblers to our groves, and sends the wild geese to the polar regions; but, when we have stated that it is an instinct, we have stated the ultimate point which our knowledge reaches, and can assign no reason why it is such.

Besides being rather rarer than most of the other grebes, this one is a more clumsy and heavy bird, and not so handsome as the smaller species. Its length is nearly a foot and a half, and its weight about a pound and a half; the bill is the same length with the head, black for the greater part of the length, but yellowish at the base. The crest on the hind head is very short, and there are no rough or long feathers on the sides of the head. This structure would lead us to suppose that this bird is less expert in using its bill in the waters than the crested ones, because almost all birds that seize their prey rapidly in the free waters, whether their bodies happen to be immersed in the waters or not, have a crest on the hind head, which appears to guide the bill in the same manner as a dart or arrow is guided by the feathers. The upper parts are of a brownish black colour, but the secondary quills and basal part of the primaries are white. The cheeks and throat are of a grey colour; the breast reddish chestnut; and all the rest of the under part white, with a fine silky gloss. Indeed, the under parts of grebes are so glossy,

so finely feathered, and so durable, that they are often prepared and used in the same manner as furs. The female differs little in plumage from the male, but the young do not acquire the red colour on the breast till after the second moult. The time of moulting in this, and indeed in all the species, is the autumn; and, so far as has been observed, there is very little difference in the summer and winter plumage. Indeed, as grebes are almost constantly in the water, and thus subject to much less variation of temperature than land birds, their differences of season are also less. Though, as already stated, these birds have not been seen, except in winter, analogy would lead us to conclude that they do breed somewhere within our shores, for we are acquainted with no species of grebe which is known to be migrant, and there are no genera of birds, so well defined and so peculiar as the grebes are, of which some species are migratory and others not. In many parts of the world, where lakes and marshy pools are better adapted to its habits, and more retired and solitary, this grebe is more plentiful than in the British islands; and there is reason to believe that it is resident all the year round in most, if not all, of those places, though there it is little observed during the summer.

**THE CRESTED GREBE (*P. cristatus*),** though more common and frequently seen than the red-necked species, is yet by no means a common bird in the British islands, and, in consequence of the drainage of many of the upland pools, it is not nearly so common at the present time as it was formerly. On the continent of Europe, and in some parts of Asia, it is far more frequently met with, though its habits unfit it for those countries which are burnt up by drought in the summer months. It must be understood, however, that, though an aquatic bird, it is not a fen bird, and therefore it is met with most abundantly in the upland pools of the midland counties, where the waters divide and run to the opposite seas. It is more aquatic than the red necked species, or, at all events, it frequents broader waters, where it is more easily seen; and there are few of the large lakes in any part of the temperate latitudes of the eastern continent where it is not to be met with. Grebes resembling this, and perhaps originally of the same stock, though partially altered by climate, are also met with in America; but the waters in North America cover such an extensive surface, that the exploring of them is no easy task, and therefore we are ignorant of the numbers and the manners of many of their habits.

This species, though handsome in its form, and not apparently so thick and heavy as the former, is a much larger and weightier bird. It measures about one foot nine inches in length, and two feet and a half in the stretch of the wings, and weighs from two to three pounds. The bill is about two inches and a half in length, which is more than the length of the head; and the colour is dull red on the basal part, and pale yellowish brown on the middle of the upper mandible and the tip; the legs and feet are dusky black, with a yellowish tint on the inner surfaces of the tarsi; the irides, and naked skin round the eyes, are bright crimson, and so is a stripe of naked skin during the breeding season, which extends from the opening of the bill to the eye; at other seasons this stripe is lead-coloured, and the tint of the circle round the eye fades; the crest is divided into two rounded lobes, and the ear-coverts

are produced, and form a sort of short ruff or mantle on the upper part of the neck; the crest and top of the head are dusky black, the cheeks are white, with the exception of a dusky streak extending from the eye to the crest; and the ear-tufts are rust-coloured, with deep black margins; the general colour of the upper part is dusky brown, with the exception of the secondary quills, and a small portion at the turn or wrist of the wing, which are white; the chin also is dusky brown; but all the rest of the under part is pure white, of exquisite texture and gloss, so that the skin of this species is highly prized for ornamental purposes. The female is rather smaller than the male, and has the crest shorter, and the colours on the upper part paler. The young, in their first plumage, are without the crest and the tufts, and have waving lines of brown on the sides of the head.

The nest is formed as near the water as possible, and generally on the side of some tufted island most remote from the land. It consists of a great quantity of herbage, and contains four eggs, of nearly the same size as those of a common pigeon; when first laid those eggs are white, but they are very soon soiled by the mire, which adheres to the feet of the parent bird when she goes into the water to feed, and also as she waddles across any sludge that may be between the water and the nest.

Crested grebes are very industrious birds, and capture great numbers of small fishes and other inhabitants of the waters. They are said to be especially partial to young eels, which form great part of the food of the young while in the nest. The slow and wriggling motion of those eels naturally render them a more easy prey to the grebes than the fishes of greater activity are. These birds are not very often seen, and it is exceedingly difficult to procure specimens of them, in consequence of the alertness with which they dive, and the short time that even the head remains above water when they come up for the purpose of breathing. They are, however, the most common of all the larger grebes; and in winter they come down nearer to the sea coast than some of the others.

**THE TUFTED GREBE (*P. cornutus*).** This species is not quite so common in Britain as the crested grebe; and it is more active as well as smaller, and therefore, not so often seen in proportion to its numbers. It measures about fourteen inches in length, and more than two feet in the expanded wings, so that it is better winged than the former. The bill is only about one inch long, very stoutly made, reddish at the base, dusky in the middle part, and greenish grey at the tip. The colours of the irides form a very certain and invariable character in this species. They consist of two circles, the inner one crimson, and the outer one white. The naked space round the eye is also white; but the streak from the eye to the gape becomes crimson in the breeding season. At this season too the reddish colour on the basal part of the bill is much brighter than at other times. The crest from which the bird gets the name of horned or tufted, the first of which is a very inaccurate expression, is divided into two pointed lobes or branches, and of a dusky colour. The crown of the head is of the same, and the ruff or ear-tufts chestnut, passing into dusky black on the margins; and both crests and tufts have a slight reflection of metallic green. The general colour on the upper part is brownish black; the fore part of the neck and breast are rust-coloured, and the sides and flanks the same, only much paler in the

tint; all the rest of the under part is pure white; the young are without the crest and ear-tufts, and the female has them smaller than the male. The breeding, general habits, and haunts of these birds, differ so little from those of the former species, that the details of them are unnecessary.

**THE EARED GREBE (*P. auritus*).** This species is still smaller than the former, being only about a foot long, and less than two feet in the stretch of the wings. The name "eared" is not very aptly applied; for the tufts on the head of this species have just as little connection with ears as those of the last mentioned species has with horns. They rise from above and behind the eyes, stand up separately behind the head, and are pale chestnut-coloured, with an orange tinge. The ear-tufts, which are very short in this species, are also orange tinged chestnut at the bases, but they are sooty black at the tips, as are also the head, nape, and upper parts generally, though broken by a few mottlings of dull brown on the scapulars and middle of the back. This black fades into chestnut all round its under margins, and that again into pure white on the middle of the under part. The irides are scarlet; and in the breeding season the streak before the eye is crimson. These birds are also very generally but not thickly distributed; and their habits bear a considerable resemblance to those of the others.

**THE LITTLE GREBE (*P. minor*).** This is in some respects the most interesting of all the grebes; and as a British species it is perhaps the most numerous. It is found in all latitudes of our mainland, where the situation suits it, and also in the islands. Its motions in the water are exceedingly agile; and in the style of its swimming it something resembles a frog, only it gets on with much more rapidity. Where the banks of the pools and streams are bare, it is rarely met with; but it is not uncommon in the humid parts of the lower country, where aquatic vegetation is luxuriant. As it inhabits nearer the dwellings of mankind than the others, it is not so timid. It is indeed a

Little Grebe.

bold and very voracious, but at the same time far from an ill-tempered bird. It has often been kept in a state of confinement, if not absolutely tamed; and if properly supplied with food, it makes a very interesting ornament to a garden pond; small fishes are

its favourite morsels ; but it will eat other animal food, and occasionally vegetables. There was one lately kept at the Gallery of the Scientific Exhibition, in the Lowther Arcade, Strand, London, which was far from being the least curious piece of mechanism in the place ; and it had the advantage of self-motion. In that gallery there is a very long trough filled with water, for the purpose of making hydraulic experiments ; and the little grebe used to dash along, around and under the floating models with great rapidity, bobbing up its head at the one end, and again at the other before one knew where to look for it. It is but an ungainly walker upon land ; but in its own element it is a very handsome bird.

The usual length is about ten inches, the stretch of the wings about sixteen, and the weight about sixteen ounces. The bill is scarcely an inch long, brown ; irides reddish hazel ; the whole upper parts are of a rusty brown ; pale on the rump ; cheeks are of the same colour as the fore part of the neck, which is grey ; in others of a light rust-colour ; breast and belly glossy white, mottled with ash-colour and light rusty ; in some the rust-colour is wanting, especially in the females ; but both sexes are subject to vary in plumage according to age ; legs dark dull green. As is the case with all the genus, the nest consists of a great quantity of materials, and the birds are in the habit of covering up their eggs when they quit the nest for the purpose of feeding ; the nest is also always so placed as that the bird can escape to the water in case of danger ; but when no danger appears the female is very constant to her eggs. Though these grebes are exceedingly voracious, as was said, and levy heavy contributions on the fry of fishes, the pike, the tyrant of our pools and slow running waters, sometimes retaliates, by seizing and swallowing the little grebes ; nor is this to be wondered at, because that fish has been known to seize the heads of swans while dabbling, and the noses of quadrupeds while drinking.

The foreign species of grebes are numerous ; but little is known of their manners, so that we shall merely mention the names of one or two.

THE PIED-BILLED GREBE (*P. Carolinensis*) is a native of North America ; brown on the upper part, and dull white on the under ; the throat black ; a white circle surrounding the eyes, and a black spot at the base of the lower mandible ; the breast mottled with olive ; the beak ash-coloured, with a black ring surrounding it about the middle ; the feet black. The length of the full grown bird about ten inches. The young have the upper part dark brown ; the sides of the neck, the belly, and the rump, reddish ; and the breast dull white with a large black spot.

THE DOUBLE-TUFTED GREBE (*P. bicornis*). A native of South America, length about twenty-three inches. The bill long and slender ; the crest divided, of a bluish black with metallic reflections ; the upper part dark coloured ; the front of the throat black ; the under part white.

PHILIPPINE ISLANDS' GREBE (*P. Philippensis*) inhabits the eastern islands. It is about a foot long ; blackish clouded with purple on the upper part, with two red lines on the cheeks and sides of the neck ; under parts blackish ash : bill ash-coloured at the base and point, but black in the middle.

THE HOARY GREBE (*P. poliocephalus*). Eleven inches long ; brown on the upper part, with the feathers on the head and cheeks produced and tipped with white ; the under part silvery white : found in some parts of Australia.

THE WHITE-WINGED GREBE (*P. dominicus*) inhabits South America and the West Indies : blackish on the upper part, greyish on the under spotted with brown ; principal quills white with brown tips ; bill black, and feet brown, a very small species, not above six or seven inches in length. There are many others, some of which are found as far to the southward as the very extremity of South America, but those which we have enumerated, must serve as a specimen of birds, whose habits are so nearly alike that size and colour are the leading specific distinctions.

GREBE-COOT (*Podiceps*). A genus of fin-footed birds, bearing some resemblance to both the genera of which their English name is compounded ; but still having sufficient characters to require their separation from both. They were at one time confounded with the darters which, however, belong to another part of the system, being entire webbed birds, and closely allied to the pelicans. The present genus consist chiefly of two species, the one African, and the other American. The characters are : the bill as long as the head, straight, cylindrical, with the point bent downward and notched, the culmen distinct but depressed ; the cutting edges of the upper-mandible a little enlarged, those of the under straight, and angular toward the point. The nasal grooves deep and long ; and the nostrils placed in the middle of each side of the bill, lengthened and entirely opened ; the feet short and placed far backward, and with the tarsi rounded, instead of being flattened and margined as in the grebes, the three front toes united by a lobed membrane, but the hind toe free ; the wings of mean length and pointed ; the first quill shorter than the second, and the second and third the longest in the wing ; the tail is very large, which forms a remarkable distinction between these birds and the grebes. Their manners have been but little studied ; but it appears that they are not nearly so aquatic as either the grebes or the coots.

AMERICAN GREBE-COOT (*P. Surinamensis*). This bird is found in various parts of South America. The upper parts are dull brown, but the crown of the head is furnished with long and pendent black feathers ; the cheeks are yellowish brown ; the sides of the neck streaked with black and white ; the eye streak white, extending the whole length of the neck ; the quills having a black band at the ends with a narrow white margin ; the bill ash-colour ; the feet yellowish brown with the lobes streaked with black and white. The length about thirteen inches. It is described as having the head and neck constantly in motion ; and it is further added, that it is a dexterous fly-catcher. Little is said of its manners, however, and it is doubtful how far that little can be implicitly believed.

AFRICAN GREBE-COOT (*P. Senegalensis*). This species is found in western Africa. It is about the size of a duck. The upper parts brown, mottled with black on the middle of the back and sides of the neck ; the top of the head and upper part of the neck blackish ; a white streak from the gape over the eye and down the sides of the neck ; all the under part white with the exception of some mottlings of black on the flanks ; tail slender, but very stiff. The manners of this species are just as little known as those of the former. These birds have got the name of *fin-foot*, which is by no means a correct one, because it is the distinguishing character of the sub-order to which they belong, or at least to several genera, belonging both to this and to other parts of the system.

**GREEN DRAGON** is the *Arum dracontium* of Linnæus, a curious North American herbaceous plant, long introduced into our gardens, and easily increased by offsets from the roots.

**GREVILLEA** (R. Brown). A fine genus of evergreen shrubs, natives of New South Wales, Linnæan class and order *Tetrandria Monogynia*, and natural order *Proteaceæ*. Generic character: calyx irregularly four sepalled, inserted obliquely; small solitary glands below the germen; stigma obliquely depressed; folliculus one-celled, which is central and two-seeded. As greenhouse plants this genus thrives well in an equal mixture of loam, sand, and moor earth, and is readily propagated by cuttings struck in sand. Above thirty species are named in books.

**GREWIA** (Jussieu). A genus of evergreen shrubs, mostly indigenous to India. They bear polyandrious flowers, and the genus is arranged in the natural order *Tiliaceæ*.

**GRIELUM** (Linnæus). A small genus of perennial herbs, from the Cape of Good Hope, belonging to the natural order *Rosaceæ*. They are impatient of moisture, requiring to be grown in sandy gravel and the pots well drained, and propagated by cuttings and seeds.

**GRIFFINIA** (Ker). A genus of bulbous plants from South America, belonging to *Amaryllidææ*. There are three species described, and, like other tropical bulbs, require a light, turfy soil, kept dry while dormant, but allowed plenty of water when growing.

**GROMWELL** is the *Lithospermum officinale* of Linnæus, a common medicinal or dyer's plant, belonging to *Boraginææ*. The lithosperma are remarkable for the stony hardness of their pericarps, which have all the brittleness and lustre of porcelain. This membrane, when analysed, is found to contain a larger quantity of earthy matter than any other organised substance.

**GROSSULARIÆÆ**. A natural order, containing only a single, though a well known, genus, namely, the *Ribes*, or *Gooseberry*. They are unarmed or thorny shrubs, with round or irregularly angled ligneous stems and branches: simple lobed, alternate leaves, but destitute of tendrils and stipules. The utility and excellence of the gooseberry and currant are well known. None of the other forty-seven species equal these, although the fruit of some others are of some importance. The berry of most of these is sweet, watery, and acid, but that of *Ribes nigrum*, and a few more, is tonic and stimulant, which appears to have some connexion with the presence of glands upon the leaves of those species. See **GOOSEBERRY**.

**GROUNDSEL** is the *Senecio vulgaris* of Linnæus, a very common European weed.

**GROVE DOCK** is the *Rumex nemolapathum* of Ehrhart.

**GRUB**. A name generally given to any fleshy dingy-coloured larva, whether proceeding from eggs deposited by a beetle, moth, or other insect. It has been attempted to distinguish grubs from maggots, by considering the former as the offspring only of coleopterous insects (beetles and weevils), and the latter as having no feet; but as the larvæ of all weevils, and many other beetles, are destitute of feet, and as the word, as generally employed, is quite incapable of strict systematic employment, we would prefer leaving it in its ordinary indefiniteness rather than limit it incorrectly, as has been done.

NAT. HIST.—VOL. II.

**GRUS**—Crane, or rather, perhaps, **GRUIDÆ**, the Crane Family, as we shall include in this article a bird or two, which are not, strictly speaking, cranes, though nearly allied to them in various respects. We have already described, in the article **AGAMI**, a species which is closely allied to the cranes, though perhaps even less aquatic in its habits.

The cranes are the first and most typical genus in Cuvier's *Cultrivorostrat*, or knifeshape-billed division of *Echassiers*, or stilt birds.

The generic characters are: the bill straight, and not very wide at the gape, and the nasal groove, which is deep, and lined with membrane, occupies nearly one half of its length; the legs are very long and strong, naked for a considerable way above the tarsal joints, and fortified with shield-like scales, which are not, however, reticulated, as in those birds which are in the habit of having their legs habitually in the water; the toes are of moderate length, the outer and middle one united by a short membrane at the base, and the hind toe is articulated so far upward on the tarsus as barely to touch the ground with its point when the animal walks; all the species have the head and part of the upper neck more or less furnished with projecting feathers; the tongue is fleshy, broad, and pointed; the wings consist of twenty-four quills; their stomach is a true gizzard; and the inferior larynx has only one muscle on each side.

By Linnæus and his followers the cranes were confounded with the herons, the storks, and various other genera, but their manners differ from these, and there is a corresponding difference of structure. Storks, according to their different species, feed more upon garbage, and those remains of animal life which are left on the subsiding of the waters in the flooded countries. They are also exceedingly voracious birds, and their gape and throat are very capacious. Herons are more exclusively fishers, and never seek their food but on the margins of the waters, into which they wade to some distance. The cranes, on the other hand, though somewhat miscellaneous in their feeding, subsist in great part upon vegetables, as the gizzard would indicate, although we had no other evidence. Cranes are also much more handsome birds than either storks or herons. They are very tall in stature, their bodies are light and elegant, their gait is majestic, and their crests are much more handsome than those of the other crested birds of the division. Generally speaking, they inhabit the warmer temperate countries, and are migrant with the seasons; but some are found far to the north in summer, at least as far as the shores of Hudson's Bay and the banks of the Siberian rivers. There are several species, each of which is worthy of a short notice; and we shall begin with the only one which breeds in Europe, and once bred in considerable numbers in England, though it now rarely appears even as an occasional visitant.

This shows that England has undergone a considerable change, not only in respect of more abundant population, but in respect of the character of the country, especially in those places which these birds frequented. Cranes are not marsh birds, but they are frequenters of the margins of marshes, though, in places where they are abundant, they spread themselves over the corn-fields, and often do considerable damage by feeding on the tender blade of the young crop.

THE COMMON CRANE (*G. cinerea*) has the body

generally of an ashen-grey colour, with the throat, the fore part of the neck, and the hind head, dusky; the crest or cap on the head, and also the quills, black. The bird is about the size of a turkey in the body, and weighs about ten pounds, but, from the great length of its legs, it is nearly five feet in height.

Common cranes are very discursive birds, and range seasonally from the north of Europe to the south of Asia and the north of Africa, and in the latter country they are said to extend their migrations as far as the Cape of Good Hope. On these excursions they fly high in the air, though they experience some difficulty in getting on the wing from the ground. Before taking their spring, they run some paces, raise themselves a little at first, and then unfold a powerful and rapid wing. In the air they form very nearly an isosceles triangle, possibly for the purpose of cutting the element with greater facility. When attacked by an eagle, or the wind is likely to break their order, they close in circles. Their passage frequently takes place during the night, which is known by their sonorous voice, which announces it, and the head of the troop often utters, to indicate the route he is taking, a cry of appeal, to which all his followers answer. Their voices, even on these nocturnal voyages, are exceedingly loud, probably owing to the length of the wind-pipe, and the convulsion near its bronchial extremity. When they cry during the day they are generally understood to forebode rain, as is the case with the cries of many other birds which feed partially on those worms which the approaching humidity brings to the surface, not only when the rain actually falls, but when, from the changed state of the air, the evaporation is much diminished. When they are peculiarly noisy and tumultuous, and fly near the ground, occasionally alighting, it is considered as a pretty certain indication of a tempest. On the other hand, when they rise high, and fly onward in regular order, it is regarded as a sign of fine weather. In getting on the wing, the apparent difficulty which they experience does not arise from the want of space in which to move their wings, for their legs are sufficiently long for allowing these to act with perfect freedom, even when the feet are firmly on the ground. They appear to run forward, for the purpose of getting an impetus of the whole body; and when that is acquired, they jerk themselves into the air by the elasticity of the legs, and move off in very good style, and they are capable of passing over many miles without alighting. When they assemble on the ground for the purpose of repose, which, after a long flight, they take with the head under the wing, they have always sentinels appointed to give the alarm in case of danger. Those sentinels stand on the one leg, as is also the habit of the storks; and the peculiar structure by means of which this resting on one foot is probably a greater relief to them than resting on both feet, because the balance is then preserved by means of the ligaments, which act by their elasticity as matter, and not by living exertion, as is the case with muscles. The distal extremity of the femur, or thigh bone, where it articulates with the bones of the leg, has a hollow or depression, which, in ordinary cases, receives a projection of the leg bones, and when this projection is received into the hollow, the bones, taken together, are shorter than when it is displaced. When, however, this joint, which is the proper knee-joint of the

bird, though the tarsal-joint is usually so called, is much bent, the projection slides out of the hollow, and bears upon a more elevated part; by this means the two bones together become longer, which lightens the ligaments, and the resistance of the elasticity of these makes the leg much firmer at this joint than if it were extended, and consequently the one leg, bent as far as it will bend at this joint, forms a very steady support. Many birds have this structure, and are able to rest on one leg for a considerable time, but none have it in such perfection as the cranes and storks.

The common cranes are understood to build in the northernmost parts of their range, and probably as far to the north as Lapland in some instances. They are very common in Sweden, and particularly abundant in the marshes of Central and Western Russia. In some parts of Poland they invade the crops, especially those of buck-wheat, in such numbers, that the farmers find it necessary to employ people to drive them off. The nests are formed in bushes and tufts of tall aquatic plants, close by the margins of the waters. The eggs are only two in number, of a greenish colour, and blotched over with brown spots.

The ancients were very familiar with the manners and migrations of these birds, and mixed them up with their superstitions. The positions of the mountains, both in Europe and in Asia, where they approximate the narrow straits which connect the Archipelago and the Black Sea, naturally bring the whole of the migrant flocks over Greece; and the plains of Thessaly, and the other more fertile parts, were, and are still, their resting-places, after crossing both the Northern and the Southern Seas. In those days the flesh of the crane was a luxury, and it is also recorded among the dishes served up in old times in England. In the old birds it is black and tough, but said to be at least tolerable in the young ones.

**THE GIGANTIC CRANE (*G. gigantea*).** This species is also styled the Siberian crane, though the name is scarcely appropriate, inasmuch as the bird appears to be found in the northern parts of both continents. It is a much more northerly inhabitant than the common crane, and in the eastern continent it probably does not get farther south in the winter than the latitudes of the Caspian and the lake Aral, while in the summer it ranges far to the north along the banks of the Siberian rivers in all places where there are marshes. In America it has been observed in the marshes near Hudson's Bay, or at all events a bird has been observed there so like that of the north of Asia that there is no specific distinction between them. It does not appear that this crane occurs in the European division of the northern migration; but it is probable that it ranges from Hudson's Bay westward to Nova Zembla, migrating with the seasons, though not reaching the tropical countries.

The general colour of this species is snowy white, with the ten first quills black, and the bill and feet reddish. It is a very majestic bird, and when it raises its long neck it stands four feet and a half high. The young of the year are of an ochre colour, with the forehead, bill, and legs, greenish brown; and very old birds have a yellowish tinge on the back of the neck. These birds have been most observed in Siberia, where they feed upon fish and lizards, frogs and other reptiles; they are very vigilant birds, shy and cunning, and it is difficult to get near them, as

they move off when the slightest noise is made or alarm given. This is, in all probability, the reason why less is known of them than of the common cranes in the more southerly parts of their migrations. The nest is constructed in the most inaccessible situations, and carefully concealed among reeds or other tall herbage. The eggs are two in number, about the size of those of a goose, ash-coloured in the ground, and spotted with pale brown. From the concealment of the nest, it is not easily discovered, but when it is, the female defends her eggs and also her young ones with great boldness, and on such occasions, from her strength, the power of her bill, and her dexterity in the use of it, she makes a stout defence against both men and dogs.

**THE NUMIDIAN CRANE (*G. virgo*).** This species is generally styled the demoiselle crane, as is supposed from the comparative lightness and elegance of its form. It is not near so large as the last mentioned species, being only about three feet three inches in height, and the form of its body is light and slender. Of the height, the legs and neck make up a very great proportion, as they are exceedingly long. The general colour of the body is bluish grey, but the crown of the head and tips of the primary quills are black. Behind the eye on each side there arises a tuft of white feathers, which unite and form a sort of crest on the occiput. From the lower neck and breast there are long and slender black feathers which hang over the others, and are very silky and flexible in their texture.

Though called the Numidian crane, and probably more abundant in Northern Africa than any other part of the world, these handsome birds are not confined to that country. During the overflowing of the Nile they are by no means rare in Egypt; and in autumn they are sometimes met with as far to the northward as Constantinople. Indeed they are met with on the southern shores of the Black Sea, the Caspian, and lakes Aral and Baikal; though it does not appear that they reach so far northward as the summer haunts of the great Siberian crane. They are found on the banks of rivers and lakes, where they feed chiefly upon fish. They are brisk and lively birds, gentle in their manners, very easily tamed, and capable of some instruction. In the wild state indeed they are very prone to a sort of dancing motion; and in confinement they may be taught to dance and perform several other feats at the bidding of their keepers. They are very attached, fond of being caressed, and strut about with apparent pride when they are noticed. In the south-east of Russia, and in the country extending thence to the Caspian, which abounds in salt lakes, they breed on the margins of these; and the females are said not to conceal their nests so much as some of the other species. They can not only be made to join other domestic birds in farm yards, but there have been many instances of their breeding freely in a state of confinement. They are hardy and also long-lived, and Buffon mentions one which was hatched at Versailles, and lived four and twenty years. There are some in the gardens of the Zoological Society of London, which are very tame; and there is no doubt that they could be pretty generally introduced wherever ornamental birds are kept with proper attention. They are very industrious and successful fishers, however, and would of course lay the fish ponds under heavy contributions.

**THE CROWNED CRANE (*G. parvina*).** This also

is an African species, inhabiting to the southward of the desert, or at least found most abundantly in that part of the country. It has been styled the Balearic crane, which appears to be a misnomer, as there is no evidence that it breeds in the Balearic isles, on the east coast of Spain, or even visits them. The rich and humid parts of Western Africa are its favourite haunts, and there it is a very tame and familiar bird. It can be tamed, and is as fond of attention as the preceding species; and the natives of Africa regard it with a sort of veneration, and endeavour to prevent it from being destroyed. In confinement it bathes frequently in cold water, and will eat either vegetable or animal food, though it prefers small fishes to every thing else. It is an exceedingly showy bird; slate blue on the upper part of the body, with the tail-feathers and quills black and bright brown, and the coverts of the wings pure white. The sides of the head are naked, and so is a portion of the throat, from which there hangs a sort of wattle, all which naked skin is rose colour, or bright red. A close round tuft of black feathers covers the front and crown of the head, from behind which there rises on the occiput a beautiful crest or crown of yellow thread-like feathers, which are twisted spirally and have black points. The bill and feet are black, and the irides are almost without colour. Its ordinary walk, though majestic and stately, is slow; but when it spreads its wings as a means of balancing itself, it can run with great rapidity. It is also a bird of long, powerful, and very elevated flight. Its cry is a loud and hoarse clang; but when pleased it can also utter a sort of clucking sound. From its form, its size, the strong contrast of its colours, its measured gait, and its familiar manners, it is one of the most attractive birds in an aviary. Like the rest, however, it is of very little value as an article of food; and therefore it can be considered only as an ornamental bird.

Respecting the other birds which resemble the cranes, less is known. They are natives of South America, especially of the plains of Paraguay; they are,

**COURLAN, or COURLIRI (*Aramus*).** The characters are: the bill longer than the head, hard, strong, compressed laterally, straight for the greater part, but slightly curved toward the tip, where it is a little enlarged. The upper mandible is slightly furrowed, and the under one is enlarged at the middle, angular, and pointed. The nostrils are linear at the sides of the bill near the base; the tarsi are long; there are four toes divided to their bases, the front ones smooth on their under sides and slender, and the fourth are articulated on the hinder part of the tarsus, but in such a manner as that it bears upon the ground. The wings are of mean length, the first quill very short, and the third the longest on the wing. Those characters indicate a difference in haunt and in habit from the cranes; and though the manners of the birds are very little known, it is understood that they are peculiar, that they do not enter the waters even as waders, or fish, but live upon snakes and other reptiles on the humid parts of the land. There are at least two known species, *A. caran* and *A. scolopacea*. The first is blackish brown on the upper part, with a tinge of purple on the back and rump, feathers on the head and sides of the neck brown with white centres; lower parts brown, spotted with white on the belly; bill yellow with black tip; irides red; and feet ash colour; length about two feet three inches. The second spe-

cies has the plumage deep brown, with reflections of red and green on the quills and coverts; the upper part of the neck white; the bill reddish ash, with a blue tip; and the feet blackish; the length about two feet nine inches.

*CAURALE* (*Eurypyga*) inhabits Guiana. The head black with white lines, the neck yellowish brown, the upper parts beautifully marked with brown, red, and yellow. It is found along the banks of the rivers, but very little is known respecting it farther than that it is a handsome bird, and does not readily fall within any genus of which there are species in the east.

*GRYLLOTALPA* (Latreille.) A genus of orthopterous insects belonging to the section *Saltatoria*, and to the family of the *Achetidae*, or crickets; the type of the genus being the *Gryllus gryllotalpa*, Linnæus, or the *Gryllotalpa vulgaris* of recent authors, generally known by the ordinary English name of the mole cricket. See the articles CRICKET and ENTOMOLOGY, in the latter of which the curious fore-leg of this insect, formed for burrowing under ground in the same manner as the mole, is represented.

*GRYLLUS* (Linnæus). Under this name Linnæus comprised a very extensive group of insects belonging to the modern order *Orthoptera* (part of the *Hemiptera*, Linnæus), and forming, in recent classifications, the section *Saltatoria*, or those furnished with hind legs fitted for leaping, as described in our article GRASSHOPPER. This group of insects, however, comprised three very distinct sections, and these have been raised to the rank of families by more recent authors, although the nomenclature of such families is very confused.

The first of these families comprises the crickets, of which an account will be found, p. 176 of the present volume. It is named *Achetidae* by Leach, but by Latreille *Gryllides*, and by Mac Leay *Gryllina*.

The second family comprises all the grasshoppers which have long antennæ. These are the *Gryllidæ* of Linnæus, the *Gryllidæ* of Leach, the *Locustariæ* of Latreille, and the *Locustina* of Mac Leay. We have already, in our article upon the CRICKETS, alluded to the incorrect application of the latter names, which ought surely to be given to the family containing the destructive locust, and which is the type of

The third family, named *Gryllus locusta* by Linnæus, *Acrydii* by Latreille, *Acridina* by MacLeay, and *Locustidæ* by Leach, which is distinguished from the grasshoppers belonging to the second family by the shortness of the antennæ, which are filiform, prismatic, or sometimes slightly thickened at the tips. To this family belong a very great number of small species, common in this country, found amongst grass and in hot sandy places, and to which the name of grasshoppers is applied, as well as to the species of the former family. Further details relative to these insects will, however, be found under the head LOCUSTIDÆ. It only remains for us, therefore, in this place, to give an account of the species belonging to the second family, or the true *Gryllidæ*.

In addition to the principal characters derived from the great length of the setaceous antennæ, the tarsi are only four-jointed; the ovipositor of the females is long and often sabre-shaped, and the upper wings of the male exhibit a glass-like area, described more at large in our article GRASSHOPPER. From the cricket family they are distinguished by the wings being deflexed when at rest; the mandibles are not

so much toothed, and the exterior lobe of the maxillæ larger than in the last-mentioned insects.

These insects, at least such as inhabit this country, are comparatively of a large size, considerably exceeding the other grasshoppers in this respect; indeed the typical species may be regarded as our most gigantic insects, although the exotic *Locustidæ* considerably exceed them in bulk, as well as in strength and compactness of structure. There are about a dozen native species, but the exotic and tropical species are far more numerous, as well as more beautiful in their colouring. Mr. Kirby united them into a single genus, to which he applied the name of *Acrida*; but more recent authors, who have extended their investigations to the entire family, including the exotic species, have established numerous generic divisions, and the native species are now distributed into the following six genera, in the work of Mr. Stephens, published during the past summer, viz.: *Ephippigera*, *Micropteryx*, *Xiphidion*, *Meconema*, *Decticus*, and *Phasgonura*. The last-named genus is distinguished by having the crown of the head acute produced in front, between the antennæ; the eyes large and prominent; the wing-covers large in both sexes, those of the males having a small ocellus; the ovipositor of the female long and straight, and the under side of the thorax armed with two spines and four lobes. This genus comprises the common great green grasshopper (*Gryllus viridissimus*, Linnæus), which is nearly two inches long, and found at the beginning of autumn in grassy places and in hedges by the sides of woods. We have found it not uncommonly in Battersea-fields. Lehmann, in his memoir "De sensibus externis insectorum," &c., p. 23, records some curious observations upon this insect, made by an Italian naturalist with a view to ascertain their powers of hearing. These insects, which fill the meadows with their singing, immediately become silent on our approaching the spot, so that it is difficult to trace their retreat, unless the greatest caution is used in seeking them. Brunelli tried various experiments with numerous individuals, which he kept in a chamber, and which kept up a constant chirping all day long. A knock at the door, however, immediately silenced them. He also learned to imitate their chirp, and when he performed this outside the door of the room, a few only would at first reply, but by-and-bye the whole joined in the chorus with all their force; on tapping again at the door, they were silent and alarmed. He also placed a male in a little cage in his garden, and set a female at liberty, which, as soon as she heard the chirping of the male, approached and leaped upon his cage, which was also the case in whatever part of the garden the female might be.

These insects are, like the locusts, herbivorous, feeding, in all their states, upon grass and herbs, although, when confined together in a small box, they will devour each other. This, however, appears to be the result of fear, rather than a natural appetite. We once caught one of them, which, being held by one of its hind legs, gave a sudden spring and jerked off its leg, which was placed with the insect in a bottle; by the following morning, however, we found that this portion of itself was half devoured. The long ovipositor with which these insects are furnished, enables them to deposit their eggs at a considerable depth in the earth, in small rounded cells. The young ones, when hatched, resemble their parents in form

as well as in activity; they are, however, destitute of wings and wing-covers. In the state immediately preceding their arrival at that of the imago, the wings and wing-covers appear as rudimental upon the back of the second and third segments of the body.

The other genera do not merit particular notice in a work like the present, being distinguished only by slight structural differences.

**GRYPHŒA** (Lamarck and modern authors). This genus of molluscs has hitherto been considered an *Ostrea*, to which in fact it bears a great resemblance, but the texture of the shell is more finely lamellar, and the peculiar characters of the lower valve, which is very deep and carinated, its summit terminated in a long spirally recurved beak, slightly turned to one side, the edge sharp and angular, and the fact of its never being attached to other bodies, or if it is, only at one small point, clearly in our opinion distinguishes it from the genus *Ostrea*, though Sowerby, in his *Genera of Shells*, points out some strong grounds of objection to Lamarck's separation. The shell is inequivalve, the lower valve very large, concave, of an oblong elongated form, carinated or ribbed, and terminating in a spirally recurved beak; the upper valve is small and flat, fitting into the lower one at a small depth from its marginal edge, another characteristic distinction from the *Ostrea*. The hinge is without teeth, it has an arched and oblong cardinal cavity, and there is only one muscular impression on each valve, as in the oyster. Recent examples are rare, and only one species is at present described. In a fossil state they are abundant. The animal is unknown. This genus is placed, in the French system, immediately after the oyster, in the first family *Ostracea*, of the third order *Lamelibranchiata*, third class *Acephalophora*.

**GUAIACUM** (Linnaeus). The *G. officinale* is a West Indian tree, which produces the medicine called gum guaiacum. Class and order *Decandria Monogynia*, and natural order *Zygophylleæ*. The wood is remarkably hard, and known in commerce as *Lignum vitæ*, so much used in turnery for ornamental purposes. The timber of *G. arboreum* is also very solid and ponderous, especially when buried, so that the natives of Cumana believe it becomes converted into stone. The plants in our stoves grow freely in a mixture of loam and moor earth, and may be increased by cuttings struck in sand.

**GUAREA** (Linnaeus). A genus of West India timber trees belonging to the eighth class of the sexual system, and to the natural order *Meliaceæ*. The *G. trichilioides* has been long an inhabitant of our stoves, and may be increased by ripened cuttings struck in sand.

**GUATTERIA** (Ruiz and Pavon). A genus of tropical shrubs and one tree, known by the name of lance-wood. Class and order *Polyandria Polygynia*, and natural order *Anonaceæ*. They are managed and increased much like other stove plants.

**GUAVA** is the fruit of different species of the *Psidium* of Linnaeus. Class and order *Icosandria Monogynia*, and natural order *Myrtaceæ*. They bear the fruits called sour-sop and sweet-sop in the West Indies, and for which they are cultivated. Several of the sorts are readily fruited in our stoves or green-houses, and are increased by layers, cuttings, and seeds.

**GUDGEON** (*Cyprinus gobicus*). A genus of soft-

finned fishes, with abdominal fins belonging to the carp family; one species only is known in the British waters, but it is probable that there may be another. With us they are found only in the slow running streams of pure water, in the southern part of the island. They are small fishes, seldom exceeding eight inches in length, and rarely as much, but they are light and much esteemed as food, especially for invalids, it being understood that they are remarkably easy of digestion. They keep near the bottom, and feed upon water insects, small mollusca, and the spawn and young fry of other fishes. They are usually found in shoals; and are so remarkable for the readiness with which they can be taken with almost any bait, that a person who can be imposed upon by shallow devices is proverbially termed a gudgeon. They spawn in May, in the shallows, it being understood that their ova require much heat to bring them to maturity, which may be the reason why they are not found in our northern or upland rivers. They afford some sport to those bungling anglers who can catch nothing else; for it is a common saying, that anybody can catch gudgeons. It is usual to collect them by scratching the bottom of the water with a rake, which brings them together in search of what food may happen to turn up for them.

**GUELDER ROSE** is the *Viburnum opulus* of Linnaeus. A well-known flowering shrub, indigenous in Britain, of which two varieties are cultivated in gardens.

**GUERNSEY LILY** is the *Nerine sarniensis* of Ker. A bulbous-stemmed fine flowering plant, common in every florist's collection.

**GUETTARDA** (Linnaeus). A genus of South American trees belonging to *Rubiaceæ*. The flowers are fine and nearly related to gardenia.

**GUILANDINA** (Jussieu). A genus of Indian shrubs, with decandrous flowers, and belonging to the order *Leguminosæ*. It is otherwise called the nicker tree, or *bonduc*, has been long in our collections, and is increased by cuttings rooted in sand.

**GUILLEMOT** (*Uria*). A genus of web-footed birds, belonging to Cuvier's short-winged or diving family; much less fitted for getting through the water than most of the others, and no great adepts at walking on the land. They are thick and clumsy birds; and very much at the mercy even of storms when in the sea. They inhabit the northern seas, and seldom come southward, except when compelled by the violence of the weather. They dive with great address, and also catch their prey with no inconsiderable adroitness. They form as it were a link between those birds which may be said to be equally fitted for the air and the water, and those others in which the aquatic habit predominates. During storms they are frequently cast ashore in a state of complete exhaustion, and sometimes they are thrown so high upon the rocks by the surge, that they are unable to get down again, or to escape, in consequence of their awkwardness and the shortness of their wings. In general, however, they endeavour to make as far to seaward as possible, and thus ride out the storm on the water. They are seldom found on the inland waters, or far up the estuaries of rivers, but when they appear in Britain, or rather in the British seas, they are chiefly on the rocky shores. On all parts of those shores they are more abundant than the divers properly so called; but they are not more productive, inasmuch as the female lays only one egg.

The generic characters are : the bill of a middle size, or rather short, very stout, straight, pointed, compressed laterally, sharp at the tip, and with a distinct notch near the extremity of the upper mandible ; the nostrils are at the base of the bill, lateral, longitudinal, half closed by a feathered membrane, which acts partially like a valve ; the legs are short, placed far backward with slender tarsi, and only three toes, all turned to the front, and webbed. The wings are short, but very closely feathered, and capable of acting like fins under the water. They are social in the breeding times, and the females place their single egg in a hole of the rock, and sometimes on the bare ledge, without even a rudiment of a nest. They moult twice in the year ; and when in their complete winter plumage, there is a little difference in the plumage ; and in this respect the young do not differ from the old birds. There are three or four species, though one of them has been separated from the genus by Cuvier, and perhaps such ought to be the case.

**FOOLISH GUILLEMOT** (*U. troile*). This species is known by a number of provincial names ; and it gets the English epithet above quoted from the fact that, in places where the birds congregate, and are seldom molested, they will sometimes allow themselves to be taken with the hand. The length is about eighteen inches, the stretch of the wings two feet four inches, and the weight from a pound and a half to two pounds. The body is of an oval form, of nearly equal thickness at both ends, which is very different from the shape of those birds which get most speedily through the air. It is, however, in great part the general shape of the grebes and divers, and also of the diving ducks ; so that it seems the best one for getting along when wholly immersed in the water. One of the most remarkable differences in external appearance between this bird and the grebes and divers, is the shortness and thickness of the neck, whereas these have it slender and graceful. The head, however, is long, and the bill pointed, and thus well calculated to divide the water before it. The bill appears much shorter than it really is, because of the feathered membranes of the nostrils, which advance half way between the gape and the tip, and thus the bird can make a wider mouth than one would at first sight suppose. The plumage on all the fore part is remarkably close and smooth, and of a blackish brown colour ; the upper part is the same but paler, and there is some white in the tips of the secondary quills ; the under part is pure white, and has the feathers as close and smooth as those on the head and neck ; and this white comes round the elbow of the wing, so that the colours are strikingly contrasted. In winter the fore neck, the throat, the chin, and partially the cheeks, become white, and the dark brown on the rest of the upper part becomes dull grey. The young birds have the winter plumage and not the summer ; and thus they are readily made different species by those who do not attend to the changes.

This species is found in all the northern seas of both Europe and America ; and when they are frozen out in the extreme north, they resort to the shores as far south as the coast of France. They are not so common on the southern shores of England, though they breed about the middle latitude of both sides of the island. In Orkney and Shetland they are met with all the year round. They approach the lonely island of St. Kilda about the beginning of February ;

and by the people there, who live much on sea-birds, and at some seasons of the year have the streets of the village paved with feathers, their appearance is hailed with pleasure. It is said that on their arrival they are caught by what seems a very shallow device : the bird-catcher lies down on a ledge of the rock during the night, with a piece of white cloth tied round him ; the birds see the cloth more easily than the rock, and alighting on it one after another, numbers of them are captured. In their favourite places they nestle thickly together in the breeding season, depositing their single egg on the bare rock : this egg is of large size, and beautifully mottled with black, blue, green, yellow, and white. The colours are, however, subject to great variation ; and in birds which build upon the exposed rocks, it is very common to see the coloured eggs which are placed high up, much paler than those which are low down. The females seldom quit the egg during the whole period of incubation, but have their supply of sprats and other small fishes brought to them by their partners. In places where sprats or herrings, or other small fishes, which appear in large shoals, are periodical in their visits, their coming is always attended by an unwonted supply of guillemots.

**THE BLACK GUILLEMOT** (*U. grylle*), is less than the former, but proportionally thicker in the body. It is fourteen inches long, about twenty-two in the stretch of the wings, and not a pound weight. Its general colours are black above, and white on the under part and cheeks, and with a white patch on the middle of the wing. It continues resident on many parts of the British shores during the whole year ; but the upper parts become so much paler in the winter, that the bird might be easily mistaken for a different species ; except during the breeding season, it is seldom seen but on or in the water. It flies low, and cannot take the wing from the ground without considerable difficulty. The feathers upon it are remarkably close, and the Greenlanders use its skin as an article of clothing, though its smell is very rank, as is also the flavour of the flesh. The breeding is very similar to that of the first mentioned species, but the egg is smaller, and not nearly so rich in the colours. The young are mottled as compared with the mature birds ; and having been observed in this state in remote places, it has been described as a different species, under the name of the "marbled guillemot." Like the former, this one is found in all the northern seas, both of the eastern and the western continent, at least so far as those seas have been explored ; and it should seem that this one especially, forms attachments for life ; for it is rare to meet with a single bird or an odd number ; and where there is a number it is usually a number of pairs, each pair keeping together, and apparently assisting each other in their fishing. It is more active as well as more shy than the former species, and therefore not so easily caught. The Greenlanders, however, do contrive to capture great numbers, which they eat with a zest, of which we can form no notion.

These appear to be the only well established species of true guillemot ; but there is another which is, generally speaking, a still more northerly inhabitant, and which resembles them in many particulars. This is,

**THE ROTCHE** (*Mergulus melanoleucos*). Cuvier gives the name of the "Greenland dove" to this bird only, but that name is also applied to the black guillemot. This is a smaller bird, being only about

nine inches long, sixteen in the extent of the wings, and five ounces in weight. Its bill is not so decidedly a fishing bill as those of the guillemots, and its wings are more powerful in proportion to its weight. Thus

The Rotche.

it is much more of an air bird, and more discursive than either of them. In summer, it is generally met with in the openings of the polar ice, dipping into the water, and probably feeding upon those small animals which inhabit the well known green-water of those seas, and are in fact the cause of its particular colour. The numbers of those birds which are met with in the extreme north, during the summer season, is almost incredible; and their flesh is represented as being much better flavoured than that of the guillemots. When they visit the British shores, which is chiefly in the winter, they remain nearer the land than the others; and upon land they walk much better. The bill in this bird is very short, not the length of the head; and therefore we may conclude that it is not fitted for following its prey to any very great distance through the water. In the summer plumage, the breast, the under part, the tips of the secondary quills, and a spot above the eye are white; and all the rest pure black. In winter, the throat, sides of the neck, and flanks, become white, and the black on the upper part changes to brownish. These alterations are seldom complete however in the birds which visit our shores, though they are understood so to be in the north. Some of them remain to breed on our most northerly islands, but by far the greater number remove nearer the pole. In their breeding, there is a difference between them and the guillemots, which would be of itself a sufficient generic distinction: the female lays two eggs, whereas no female guillemot lays more than one. Those eggs are of a spotless green colour, and never placed but in some hole or crevice of the rock.

GUINEA PEACH is the *Sarcoccephalus esculentus* of Afzelius. A cultivated fruit of Sierra Leone. It belongs to the fifth class and first order of Linnæus, and to the natural order *Rubiaceæ*.

GUINEA PLUM is the *Parinarium excelsum* of Don. A lofty fruit tree common at Sierra Leone. The genus belongs to the *Chrysobalanææ*.

GULL (*Larus*). A genus of web-footed birds, belonging to the long-winged division, and one of the most characteristic which are to be met with on the sea. They are exceedingly numerous, much on

the wing, and particularly noisy. They are birds of powerful wing, and also well adapted for walking on the shores, and some of them migrate inland at certain seasons of the year, and in certain states of the weather. Those which have this habit mingle freely with land birds in seeking their food on the newly-ploughed lands near the sea. They find their sea-food indiscriminately in the waters and on the shores; and when they alight on the water they can ride buoyantly so as to rest themselves. But they are air-birds rather than aquatic ones, though they derive the principal part of their food from the sea.

Gulls are found on the shores of all latitudes, and they are very discursive, and often met with far from the land, not so far, indeed, as the albatross, the tropical bird, the petrels, and some of the terns, but still a considerable way from the shores. When those birds which are discursive over the sea are taken by severe gales, they have no such means of rest as land-birds have under similar circumstances. Generally speaking, the land bird can get some shelter, some elevated object which the wind does not agitate, in the lee whereof it can pause with some sort of repose until it recovers its powers; or, even if it cannot do this, it has the solid ground on which it can crouch down, and there in so far recover itself, while the wind sweeps over it. On the sea, however, there is no such refuge for a weary wing; and, therefore, those birds which are discursive upon the broad waters are much more buffeted by a gale, when caught in it, than the land birds are. The wind sweeps over the surface of the waters with much more velocity, in proportion to its general violence, than it does over the surface of the land, because, from the general level of the watery surface, and also from the extent to which it yields to the action of the wind, there is far less friction between the air and the water than there is between the air and the land, whatever surface the land may have. Any one may be convinced of this by standing, first on the lee, and then on the windward shore, of even a moderate expanse of water, say a river not broader than that one can readily see across it. Standing on the windward shore, it will appear to be only a moderate, or, at all events, a brisk gale; while standing on the lee shore, when the wind comes from the water, it will appear a violent tempest. The difference of violence will also tell in the different degrees to which the surface of the waters is agitated. On the windward there may be barely a ripple, while leeward there is violent agitation; and there is a gradual increase of the waves all the way, clearly proving that the wind gains power in blowing across the water, which it does not gain in blowing across the land.

In the case of gulls, and other air-birds of the sea, which, though they go to considerable distances, are not absolutely "far at sea" birds, but merely coasters which venture a good way from the land, though they still own that land as their home, they are always taken on a lee shore when a storm gets the better of them. If the wind blow from the land, they can fly against it, and so make for the shore, with considerable labour, no doubt, but still without any drifting, such as happens to them when they attempt to fly before a wind with which they cannot keep pace. Indeed, it is only such a wind that completely takes the power out of those birds, and so drives them before it, like wingless things, until their mere gravitation

(their wings having lost all power) brings them down to the surface of the water. This often happens to the gulls, because, in those seasons when they are most discursive, that is, when they associate to visit their breeding-places in the spring, and when they take their departure from them in the autumn, the winds are most inconstant.

The birds are no doubt well protected, by the nature of their plumage, when the wind deprives them of the use of their wings, and brings them in contact with the water; and though the water is in agitation, and the waves are swinging in mountains, or yeasting high in broken water, there is still a safety for the sea-birds on the surge which those who have not studied the matter are probably not aware of. It is true that the gulls, and other surface-birds which do not dive, and thus penetrate the curling crests of the waves, have not so much safety as the divers; but still there is one part of the wave upon which the storm-beaten bird can find shelter, and generally also food. This is a very curious circumstance in the agitation of the sea, and it holds even at great distances from the shore. Waves are merely vibrations of the water, and in the slope of each wave, somewhere about the middle of its height, or in a line, if the wave is linear, which does not partake in the violent motion with which the crest and the hollow alternately change places. The wave turns upon this point or line, just as a vibrating balance turns on its axis, or as a pendulum swings on its point of suspension. This centre of motion in the vibrating wave is comparatively at rest; and as it is approached either from the ridge or the hollow—and it is of little consequence which, for these alternate with each other—there is comparatively little motion of the water. It is true that, in violent gales, more especially when they blow in gusts, waves are never simple; and thus the centre of one wave, which, if there were but that one, would be a point of comparative rest, is itself in motion upon another wave. Notwithstanding those circumstances, there is a most convenient resting-place for the sea-bird upon the troubled waters; so that it actually is in less danger, and suffers less fatigue, than if the surface were waveless under the same violence of the wind. Indeed, if we were to suppose a gull, which can ride in the storm till it has recovered itself, to be placed on smooth ice, and even half the violence of wind to beat upon it, it would be swept away like a thistle-down, and destroyed by the violence of the motion. But, upon the point of motion in the wave, the turning point, as it were, the bird rides secure, and in the alternations it has the shelter of the lee, and when it is most exposed to leeward, the wind only beats it against the soft resistance of the water, without much tendency to drive it from its place.

This circumstance is well worth attending to by every one who wishes thoroughly to understand the economy of the long-winged sea-birds, and how well they and the water and the storm are tempered to each other. In almost every account which has been written, even by eye-witnesses, of the conduct of gulls and similar birds, when unable to keep the sky in a gale, there is wonder expressed at the miraculous escapes which the creatures make. As seen from the shore, they appear at one moment to be whelmed in the foaming crests of the waves, and plunged to utter destruction; but, no sooner does the vibrating wave turn, than they are found upon the lee side, rocking

in perfect security, and without a single feather being wetted. Not only this, but that every vibration of the wave, and the consequent rest, or comparative rest, of its centre of vibration, brings food to the birds. The little fishes, the small floating animals, and the general waste of the sea, are all thrown to this point; and one who has the opportunity, and attends carefully to the action of gulls, may often perceive them floating and feeding at their ease amid the turmoil of very formidable waves. So beautifully does nature adapt every creature to those circumstances in which she places it.

We have mentioned these circumstances, because the gulls, from their size, their numbers, and their general distribution, are the birds in which they may be most easily verified by direct observation; and, having done this, which forms a most interesting study at those times when the sea is most worthy of being studied, we shall proceed to make a few remarks on the birds themselves. There are two distinct genera to which the common English name of gull is given. They have not much in common, farther than that both are air-birds belonging to the sea; and, indeed, they stand in so opposite relations to each other, that, while the one genus are "gulls," the other genus are "gullers;" that is, they live by plundering the gulls properly so called. We shall, however, save some room, and make our account of them both more complete, by taking the two genera consecutively in one article. The *gulls*, properly so called, form the genus *Larus*; and the others, the *skuas*, form the genus *Lestris*, that is, robbers or plunderers.

**GULLS PROPERLY SO CALLED (*Larus*).** These are often divided into two sections; but, as the divisions consist only of those which are larger, and those which are of smaller size, they are of little consequence. We shall, therefore, consider them as one only. The generic characters are: the bill long, or middle-sized, strong, hard, compressed, sharp-edged, hooked towards the tip, lower mandible forming a salient angle; nostrils lateral, in the middle of the bill, longitudinally cleft, straight, and pervious; legs slender, naked above the knee; tarsus long, three fore toes quite webbed, the hinder free, short, placed high on the tarsus; tail-feathers of equal length; the wings long. The birds of this genus are diffused over almost every maritime country; but in the northern and southern extremities of the world they breed most freely, and with least disturbance. Flocks of them haunt the sea-shore in search of living or dead fish; and such is their voracity, that scarcely anything comes amiss to them, for they will greedily feed on putrid carcases of whales, and the refuse of the tide, and they will contend with one another for the most loathsome fare. In the eager indulgence of their ravenous propensities, they swallow the hook along with the bait, and, like other predacious birds, they throw up pellets of feathers, and other indigestible matters; nay, when harassed or alarmed, they with great facility bring up their food, and, should they be allowed to recover from their surprise, they will again swallow what has been disgorged. Like all voracious animals, gulls are capable of enduring hunger for a long time; and though their favourite food is animal substances, want will bring them to feed readily upon vegetables. The old ones are generally unbroken in the colours of their plumage, though different parts of the body are of different colours. The young are

almost invariably mottled, and as they do not acquire the adult plumage till three years, and differ a little in each year, there has been a great deal of unnecessary multiplication of species. The full-grown ones moult twice in the year, and the principal seasonal distinction is more white in the winter than the summer. Between the sexes there is little difference, except that the male is larger than the female. Some species breed on the cliffs, and others in the marshes and by the margins of the pools inland, it being understood that the rock-breeders are more exclusively fishers, while the marsh-breeders feed more upon garbage, worms, and other small animals. All of them are, however, very miscellaneous in their feeding, and they have been not inaptly styled the vultures of the sea. When they congregate in numbers to breed, they are exceedingly clamorous; and they often collect at other times in vast numbers at particular places of the shore, when they are equally noisy. It is understood that these clamorous meetings are certain indications of bad weather, more especially when the marsh-breeders quit the sea and fly inland. The flesh of old birds of all the species is tough, and rank in the flavour, though it is readily eaten by the Greenlanders, the Esquimaux, and other tribes of the extreme north. The fact is, that the flavour of rancid fish-oil, which is so offensive to us, is the choicest relish to these people. The young of some of the species are sold in the markets in various parts of this country, and are not unpleasant food. The eggs of many are also eaten in great numbers. There is still some doubt as to the number of species, and, from what we have mentioned of the changes of colour, the subject is one of considerable difficulty, therefore we shall mention only the principal ones.

**BLACK-BACKED GULL** (*L. marinus*). This species is found generally diffused over the seas of both continents and in both hemispheres; though on our own shores at least it is not so plentiful as several of the others, occurring most frequently in pairs, and seldom in flocks of more than a dozen. It remains in

associate with the other gulls, and seldom admits them near its haunts. It feeds chiefly upon fish, but it also attacks ducks and other birds. It is exceedingly ravenous, attacking all manner of garbage and carrion, whether cast on shore or floating on the water; and it will often tear fish from the hooks on the fishermen's lines. Its usual cry is exceedingly harsh. The young may be tamed; but they require a great deal of food, which they devour so greedily as to remain for a considerable time afterwards motionless, with the head almost buried in the feathers. The greater number of the northern ones breed far north; but there are others which breed on the shores of England, as far south as Lundy Isle in the Bristol Channel. The eggs are three or four, of an olive colour with spots of dark brown and purple; they are eaten, but they are not very palatable. The northern people eat the young, and use the skins of the old birds for clothing.

**BURGMASER GULL** (*L. glaucus*). This also is a large species, though smaller than the former. It is about twenty-eight inches long, more than five feet in the stretch of the wings, and weighs about four pounds and a half. In summer the back, shoulders, and coverts of the wings, are bluish ash; and the quills have white shafts and tips. The bill, which is very long and strong, is of a fine yellow, with a scarlet spot on the angle. The irides are yellow, and the naked margin of the eye is red. In winter the head is mottled with brown; and the young birds are mottled with light brown and white. All the parts of the plumage, except those which have been mentioned, are pure white. This is a very voracious bird, common in the northern seas, but rare in temperate latitudes. It sometimes visits Holland, and occasionally, but rarely, the British islands. It is described as a rock breeder, and the eggs are said to be greenish with black spots. It is in winter only that the burgomaster comes southward.

**THE COMMON GULL** (*L. canus*). This is the "wild sea-mew" of the British shores; and though it is not so landward as some of the others, it is found on most parts of our shores. It is about seventeen inches long, and thirty-six in the stretch of the wings, weighing about a pound. In the mature bird the back and scapulars are clear bluish grey, the primary quills black, and the secondaries grey, both with white spots on the tips. The young are subject to considerable changes of plumage in their successive years, and have been described as different species. The common gull is not a rock breeder, that is, it does not breed on the high cliffs, neither does it retire to the inland marshes, it breeds in concealed places along the shores. The eggs of the common gull are two in number, nearly the same size as those of a hen, but of an olive brown colour, marked with dark reddish blotches.

Common gulls are more completely scavengers of the sea than any others of the race which frequent the British shores. They do not refuse fish where such come in their way; but they watch more for the offal both of the land and of the sea. Near the estuaries of large rivers, especially that part of them where the water of the estuary meets the tide, and the animal remains produced by both are accumulated, they are found in greater numbers than almost anywhere else. They, however, distribute themselves generally along the beaches where there is an alternate covering and uncovering of the bottom to some

Black-backed Gull.

the same haunts all the year round, but those haunts are rather particular spots. It is the largest species of the genus, measuring at least two feet and a half in length, and six feet in the stretch of the wings, and weighing about five pounds. The shoulders are bluish black, the feet flesh-coloured, the bill yellow with a red spot on the projecting angle of the lower mandible. The quills are black, marked with white bars, and have white tips. The young till the third year are mottled with brown and white. It does not

extent, because much more food is left for them there than where the shores are abrupt and precipitous. They also throng about the fishing villages, where there is usually a great deal of garbage, and where in consequence the common gulls are scarcely less familiar than poultry are in the inland villages. It appears also that they know instinctively where there is food for them on the land as well as where food is most abundant for them at sea; for though the times when they leave the shores *en masse* are understood to be those immediately preceding storms, yet they

Common Gull.

visit the fields at other times when bad weather certainly does not follow their appearance. They are tamed without much difficulty if supplied with plenty of food, which indeed is the case with all rapacious birds. In places near the sea tame ones are very useful in gardens, which they clear of slugs, worms, and other destructive little animals, very successfully; and in such places they will pay their regular visits to the sea, and return of their own accord. On emergency they can be made to eat grain; but that is not a favourite food with them. As is the habit of all gulls, they disgorge the contents of their stomachs when alarmed, and if the alarm is soon over they re-swallow. Whether this arises from the attacks made on them by the skuas it is impossible to say, because there are many sea birds which the skuas do not assail that have this habit. The petrels, for instance, always discharge a quantity of oil from their stomachs when they alight on a ship, or get into any other unusual situation. The flesh of these birds is not relished by most people; though some of those who reside near the sea consider it as not unpalatable after having been buried for four and twenty hours in fresh mould and then washed with vinegar.

**KITTIAKE GULL** (*L. tridactylus*). This species is about the size of a pigeon; fifteen inches in length, about three feet in breadth, and more than half a pound in weight. The adults in their winter plumage have the upper parts bluish ash; the cheeks finely striated with black; the exterior quills bordered and terminated with the same; some black on the other quills; and all the rest of the body white. The bill is greenish yellow, and the feet olive brown. The leading character is the absence of a hind toe, in the place of which there is a mere clawless tubercle. The manners of these birds are peculiar. During the winter season they quit the shores, and are understood to disperse themselves over the northern seas, where their chief place of repose is on the ice. In spring they return in vast crowds to the rocky shores, where they breed in society, and literally encumber the air

with the multitude of their wings. On the cliffy parts of the east coast of Britain they are exceedingly numerous, so much so that any number either of the young ones or the old ones may be caught. They often sit so thick upon the rocks as to make these appear from a distance as if covered with snow. Their eggs are sought after with some avidity. They form nests constructed of coarse vegetable rubbish. The eggs are deposited in June, of a dingy greenish or whitish colour, marked with ash-coloured spots. When the young have left the nests, but are unable to fly, the shooting of them is a favourite sport in places where they are abundant. It is said of them, as it is of smoke-dried gannets, that they serve as a whet to the appetite; but an epicure who despatched a dozen upon one occasion, declared that he had no more appetite when he left off than when he began. They are more gentle in their manners, and as it is said more cleanly in their habits, than several of the other gulls, and instances have been known of their being tamed and evincing considerable affection for their masters. As they are among the most elevated breeders of all the gulls that frequent our shores, as their breeding rocks are usually of the most sublime description, and as the birds themselves are very numerous and by no means unhandsome, they are worthy of being studied with considerable attention.

THE SILVERY GULL (*L. argentatus*) is also called the herring gull. It has the feet of a pale flesh-colour; the irides and bill yellow, the latter with an orange spot on the angle. The upper part is bluish ash colour, and the quills dusky with black tips and some white spots on the back; the sexes are alike; the young have the bill of a horn colour, and the plumage mottled. The quills, in this young state, are dusky, without any black on the tips, or any white spots; and this plumage continues with very little alteration till the autumn of the second year. At that time, the feet acquire a reddish tint, and the bill becomes yellowish, the white is a little more pure, and the mottlings more of an ash colour. The dusky hue which, in the first plumage, marks the end of the tail, also begins to break with white at this moult. In the third autumn, the entire ash colour, and white, with the black on the tips of the quills, the white spots, the flesh-coloured feet, the yellow bill, and the straw-coloured eyes, are acquired, after which there is no farther change in the plumage. In the spring of each year, while the bird is advancing to maturity, there is some change in the plumage, but it is very slight, thereby proving that though the gulls do moult twice in the year, the grand moult is the autumnal one.

In all their plumages these gulls resort to the breeding grounds in the season; and as they do not congregate on those grounds at any other time of the year, there is little doubt that they breed before they assume the adult plumage. This is not uncommon among several genera of aquatic birds; and it used to be considered as a conclusive argument that the young and old were of different species. These birds are very abundant and very generally distributed over the shores, not only of the seas, but occasionally of the inland lakes. The greater number breed in the north, and form large nests of dry herbage on the ledges of the rocks. In the Orkney and Shetland islands their nests are exceedingly numerous; and when the herring fishing sets in they are such constant and such numerous attendants, ready to snatch

their share of the produce, that the fishermen can hardly drive them away. In winter they range considerably southward, and are not uncommon about some of the lakes in Switzerland, and farther east they reach the Black Sea, the Caspian, and the Mediterranean; while on the American shores they range as far southward as the West Indian islands. They get the name of herring gulls from the fact of their being seen in vast clouds hovering over the shoals of herrings, keeping up an incessant clamour, and as occasion offers darting down and twitching out of the water those fishes which are near the surface. The flesh of this species is like that of most of the others, tough and unsavoury; but in those Catholic countries where it is found in the spring months, it is sold in the markets during Lent, as belonging to that class of birds which the pope and cardinals have seen meet in their wisdom to consider as fish, and allow to be eaten at all times when the flesh of such birds as are not *catholically* fish is prohibited under the most enduring penalty.

THE IVORY GULL (*L. eburneus*). The ivory gull is not only the most beautiful of the race, which are upon the whole rather handsome birds, but it is one of the most beautiful of sea-birds of whatever genus. It dwells in the extreme north, and does not quit the icy seas unless compelled by the violence of the weather. It appears only occasionally, and indeed as a straggler, on the most northerly islands belonging to Britain; for when driven southward by a winter of more than usual severity, it generally dashes onward to a greater distance. It occasionally alights in Holland, against which the winter winds from the polar sea set much more directly than they do against the British shores; and this is the reason why some polar birds which are rare with us, not only visit Holland regularly during the winter, but extend their migration up the valley of the Rhine as far as the Swiss lakes. With us the winds of the polar sea are turned by that general westerly or south-westerly current of air from the Atlantic, which, though it deprives us of the visits of those northern birds, gives us a much milder winter than the same latitudes of the continent. The length of the ivory gull is about twenty inches, the wings at least four feet, and the weight upwards of a pound. It is a bird of very elegant form, and perhaps there is no wing which cleaves the air with so much apparent ease as that of the ivory gull. Its colour is equally fine; it is of the most intense, and indeed indescribable white, far purer than the snows of its native regions; and nothing can exceed the compactness, the softness, and the exquisite gloss of its plumage. Though it is called the ivory gull, ivory, or indeed any other substance with which we are elsewhere acquainted, gives but a faint notion of its extreme purity. The feet are dark coloured, with the tarsi very stout, and the tibiae feathered down to the tarsal joint, whereas in most of the other gulls there is a considerable extent of garter or naked space above this joint. This species is a marsh breeder, but breeds only in the extreme north, though there it is understood to range round the entire circumference, being as common between Asia and America, as it is between the latter continent and Europe. The young, of which the particulars are not very accurately known, are said to be mottled, with the black predominating in the first year, the white in the second, and acquiring their entire plumage in the third. It is probable that the appearance of some of those mottled

ones in places pretty far to the south, and also that some of the other gulls breeding southward in their immature plumage, may have led to the statement made by some of the continental ornithologists, that those gulls generally breed in the south of Europe. On the contrary, there is no reason to believe that a single nest of this species was ever found at any distance, if at all, without the polar circle. We might be prepared to expect this from the character of the feet, and also from the intense and unbroken whiteness of the colour. There is no southerly breeding gull, which has the feet feathered as these birds have, so as to endure the utmost severity of the winter's cold; and there is no gull which breeds in the south that has the plumage on the upper part so well suited for resisting alike the intense cold of the winter, and the continual action of the summer's sun. The nest is described as being on the ground, rudely constructed of vegetable remains, and the eggs as being four in number, and of a white colour.

LAUGHING GULL (*L. ridibundus*). This is a well-known species, and one which is very generally distributed. It is a bird distributed over many latitudes; and where there are marshes and pools, it resides as much of the year inland as on the sea. In summer, they collect in great numbers at favourite pools, especially those which contain islands, for the purpose of breeding; and at those times tadpoles and other productions of the water, together with worms, slugs, and other things which they pick up on the humid grounds, form the chief part of their subsistence. There are some places, both in England and in Scotland, where they still breed in great numbers, but more abundantly in the latter country. It is not easy to find out what circumstance may determine them in those parts where they have their nests; for there is a place in Strathmore, where pools of considerable extent, containing islands, many tufts of herbage, and to a great extent concealed by plantations, are very numerous, and, to all appearance, equally well adapted for the nesting places of those birds; but from time immemorial they have resorted to one particular part in such numbers, that, when they are alarmed, and take the wing, they appear from a distance as if it were the smoke rising from some mighty cauldron. But while they are thus abundant, to absolute crowding, on this particular pool, it is rarely that an individual is seen upon any of the neighbouring ones, and there never is a nest anywhere but at this one spot. This little lake is also far from being the most secluded; for one side of it is open to the cultivated fields, and not very far from human habitations. The birds, however, do not appear to heed this, for they alight near the houses with all the familiarity of magpies, and search the fields with the same assiduity as rooks. What may be the absolute quantity of specific service which they perform to the farmers, it is not easy to say, but it is a fact that, in that particular part of the country, the crops rarely, if ever, suffer from grubs or other ground insects. The birds, in their chosen habitation, are exceedingly noisy, and their cries are plaintive and wailing, but still they give a lively and picturesque effect; and it would be pleasant to see gull-pools in more parts of the country. The length of this species is about fifteen inches. The colour of the adult on the upper part is clear bluish ash. The head, the neck, and the wing-coverts, pure white; a black spot in front of the eyes, and another on the ear-coverts;

the outer edges of the quills and tail-feathers pure white, and the rest of the plumage white, with a rosy tinge. The young are mottled with brown and white, and have the tips of the quills and tail-feathers black. They pass however through two changes of colour, like the rest of the gulls, and therefore they are apt to be mistaken. These birds are easily domesticated, and are very ornamental as well as very serviceable in gardens, by clearing them of slugs, snails, worms, and other destroyers of vegetation, while the birds themselves injure nothing. It is understood, that contrary to the habit of the others, which admit of being thus kept, these birds do not require to visit the sea, though they must be fed artificially during the winter, an attention which their summer labours well repay. For winter food bread soaked in milk, or even in water, is very suitable for them; and they are not so voracious as the larger and more seaward gulls.

In the winter season they resort to the sea coast, but it appears to be chiefly from want of food; and though they can swim, and are often seen flying over the waters, watching for what the sea may cast up, yet they are as frequently met with in company with the running birds along the beaches. In the breeding season they are very plentiful in Cambridgeshire, and in some of the fens of Lincolnshire, resorting to the most swampy parts, along with ruffs, red-shanks, and snipes, whose nests are intermingled with the tall tufts of bog-grass. The gulls trample down the grass on the tops of the small insulated hillocks, and there form a flooring for their eggs, which are generally three or four in number, and usually of a deep olive colour, mottled with brown, and dusky blotches; but they are liable to vary. The females sit insulated on these about a foot or rather more above the swamp or surface of the water. Though thus seen at a considerable distance, they can better observe the approach of an enemy, and cannot be so easily shot. At the ceremonious feasts of the great in former times, the young gulls of this species were served up at the tables. There is considerable interest about these birds, as being one of the links which more immediately connect together the birds of the fresh waters and those of the sea.

**ICELAND GULL** (*L. Islandicus*). This species bears considerable resemblance to the burgomaster gull, formerly described, only it is smaller, more handsome in its form, proportionally longer in the wings, and altogether a more handsome and a more active bird. The colours are nearly the same in their distribution as those of the burgomaster, only the ash-colour on the back is paler and purer in the tint. The bill is much shorter and far more slender; the brown in the plumage of the young birds is also paler. This species does not appear even in the northern parts of the British islands, except as a rare winter visitant; and there is not much known of its manners in its native north. It is understood to be a rock breeder, and to nestle in the cliffs of Iceland, Jan Mayen, Spitzbergen, and Greenland.

**SMALLER BLACK-BACKED GULL** (*L. fuscus*). This species is sometimes called the herring gull, as well as the one already mentioned, but much darker; and there is one peculiar character by which it is distinguished from all the other gulls. Its feet are yellow, while in the others they are reddish or dark coloured. The upper parts are deep bluish grey, or slate black; the top of the head, the region of the eyes, the hind head,

and sides of the neck are white, streaked with lines of clear brown; the forehead, lower part of the back, tail, throat, and all the under parts are pure white; the closed wings extend two inches below the point of the tail, having the quills black with white tips, which form a spot on each side; the wing-coverts are also blackish with white tips; the irides and bill are yellow, the latter with a red spot on the angle of the lower mandible; and there is a red spot round the eyes. The bird is about twenty-two inches long, and weighs about as many ounces. The young have the upper parts mottled with brown and yellow, the bill blackish brown, and the feet dull yellow. These birds are very generally distributed over all the northern hemisphere, perhaps more so than any other of the gulls: their habits are very similar to those of the silvery gull; and like that they follow the shoals of herrings, and thus have an equal claim to the appellation of herring gulls. They breed in great numbers on some of the rocky shores of the British islands, more especially in Orkney and Shetland, but they are found on the Black Sea and the Caspian; and indeed generally wherever the place is adapted for gulls, even as far to the southward as the tropic, and occasionally within it.

**THE BLACK-HEADED GULL** (*L. atracillus*). This gull is about the same size as *ridibundus*, so that the two have often been confounded together; and one principal cause of the confusion appears to be, in the winter, the time when they are most seen by naturalists and describers, the characteristic differences of their plumage are considerably faded. This species has the bill and feet deep lake red, while those of the laughing gull are bright vermilion. The laughing gull also has white on the primary quills, while this bird has none; and the head of this one is far darker in the summer, being almost black. It is a very handsome bird, and the colours contrast strongly with each other; the cape upon the head, which extends a little way down the neck behind, is not absolutely black, but very deep lead-colour; the rest of the upper part is lead-colour, but not so dark as the cape; the quills are deep black, without any white, and the under part is altogether white, with very delicate reflections of rose-colour, which last fade off in a very short time after the bird is killed. In winter the forehead becomes white, with the exception of a few feathers at the base of the bill; the upper parts also become grey, with the exception of the primary quills, which merely change to a deep brown, differing little from black; in the winter plumage the under sides of the wings, as far as the primaries, also become silvery white, giving a remarkable appearance to the bird when it is seen from below, and, for that reason, this is the gull which is most generally introduced into paintings of the sea, whether those paintings happen otherwise to represent its localities or not. Its localities are, however, pretty extensive; for, though its head-quarters are in the North Seas in the breeding season, it finds its way as far as the Mediterranean in winter, and that in considerable numbers. It is a rock-breeding bird, forming its nest in the same way as the silvery gull, and indeed resembling that one very much in its general manners.

**BROWN HEADED GULL** (*L. capistratus*). The characteristic distinction of this species is a brown mark on the upper and hind part of the head. The bird is about fifteen or sixteen inches in length, but

it is much more slender in its form than the black-headed gull; the bill and feet are also much smaller than in that species, and indeed proportionally smaller than in any other of the gulls, so that they make a partial approach to those of the terns, and, as we might expect, there is a corresponding approach in the manners of the birds; for this gull is much more habitually seaward, captures its food more exclusively when on the wing, and, consequently, is less on the beaches, and feeds less upon garbage, than most of the genus. It ranges over the northern seas, and, though not common on our southern shores, it is by no means rare in the north. The bill, the feet, and toes, are brownish red, with the webs of the latter brown; the top of the head is purplish brown, terminating in black, but not extending so far over the head as the cap of the black-headed gull; there are also a few mottlings of white in the front margin of the cap; the neck, breast, and all the under parts, are pure white; the upper surface of the wings is pale greyish ash, and the under greyish white; the primary quills are white in the centres, margined with black, the black margins being broadest on the inner webs. Its colours are understood to be subject to the same winter changes as those of the other gulls, and the young to have the same kind of mottled plumage, only varying with the tint of the old birds, for the darker mottlings of the young are always paler in those species which have the entire colour paler in the old birds; and this is one means by which, when they are all mottled, the young of the different species may be distinguished from each other. From the lightness of its form, the softness of its colours, its habitual motion on the wing, and its frequently twitching down to snatch from the waters those small substances on which it feeds, this is far from being the least interesting of the gulls.

**SABINE'S GULL** (*L. Sabini*). This bird is an inhabitant of the extreme north, and has the legs feathered, though not to the tarsal joint, as the ivory gull has. Its structure, however, indicates a far northern bird, the length of the tarsus being an inch and a half, and the tibia feathered as already stated. These are small gulls, breeding in the dreary islands on the shores of Greenland, and associating with terns and other birds. They are described as picking up the principal part of their food along the water-line on the beach, and seldom fishing. They live in society, numbers of them breeding at the same place, and they defend their young with great resolution. The eggs are two in number, placed on the bare ground near the margin of the waters, and not high upon the rocks. These eggs are about an inch and a half in length, rather rounded at the ends, olive in the ground colour, but thickly blotched over with brown. They are hatched about the beginning of July, and the pairs are remarkably attached to each other. No account of a very satisfactory nature has yet been obtained of the changes to which they are subject in the winter.

**LITTLE GULL** (*L. minutus*). This is by much the smallest of all the gulls, being only about two inches in length, but it is a well winged little bird, and very discursive over the sea. It does not come to the British islands except as an occasional visitor. It appears also to be more a Siberian bird than an inhabitant of the Atlantic seas. The plumage of the adult birds, in the winter, is bright bluish ash on the upper part; hind head, nape, and patch on the eye

and ear, dark ash; quills bluish, with a large white bar on the tips; coverts of the wings, and all the under parts, pure white; bill and irides brown; feet red; the wings extend an inch beyond the point of the tail. In the summer plumage, in which it has been described as the Siberian gull, it has a black cap on the head, and a spot of the same colour behind the eye, and the wings ash-colour, with white tips. The young are mottled.

**ASH-HEADED GULL** (*L. cirrocephalus*). This is described as a Brazilian species, but, in all probability, it ranges over great part of the Atlantic. It is fourteen inches in length. The bill and feet are red; the upper parts, and the throat and neck, are bluish ash; the forehead white; the first seven quills of the wings black, with white at the bases, and when the wings are closed, the black feathers project beyond the coverts, forming a spot on each side; the coverts, the tail-feathers, and all the under parts of the body, are pure white.

Many other species and varieties have been described as inhabiting the seas of different parts of the world, but little is known of them farther than has been obtained from the inspection of a few museum specimens; and it does not appear that there is any great difference of habit among them which may not be found in one or another of the species that have been enumerated. At all events, these include the whole that have hitherto visited the British shores either habitually or occasionally. We have been somewhat minute in our notice of them, as gulls are birds which are highly characteristic of the sea, and peculiarly attractive to those who only occasionally see the great waters. When a "sea-bird" is mentioned by way of eminence, a gull, a tern, or a petrel, is always meant.

**SKUAS** (*Lestris*). Though, in the northern parts of these islands, the places where the people are most familiar with sea birds, and most interested in them, the members of this genus are called gulls, and though the older naturalists included them in the genus *Larus*, yet they are quite distinct both in their structure and their habits; and we have introduced them here because it will not only save repetition, but enable our readers to see more clearly the relation between them, which is in some respects a curious one.

We mentioned that the gull may be considered as a sort of vulture of the sea, and partakes of the voracity and cowardly, or rather inoffensive, character of the land vultures, although the great black-backed gull is alleged to take advantage of the weakness of living prey, in the same way as is said of the condor. There is another point of resemblance between them which is perhaps as striking, and that is the great length and curvature of the wings, both in the gulls and the vultures, which appear to fit them for floating long upon the wing, and seeing their prey at great distances.

Now as the gulls are thus, to some extent, the vultures of the sea, so the skuas may be regarded as to a similar extent the eagles and hawks of the same. They are strong, bold, and plundering birds; and besides their peculiar mode of plundering the gulls, to be hereafter noticed, they rob other birds of their eggs, and commit various depredations, which conduct on their part has, not inappropriately, gotten them the generic name of *Lestri*, or robbers. In their breeding places, which are in countries far to the north, rarely if ever to the southward of the Orkney

islands, the larger ones repel all intruders with great resolution, and are formidable even to man himself. In this they differ from all other sea birds, many of which are very clamorous when their nesting places are invaded, as for instance gannets, cormorants, and all the species of rock-building gulls. With these, however, it is only clamour; but the larger skuas can make formidable attacks, and their numbers overcome the sea eagles themselves. But while they are thus bold in the defence of their homes and broods, they are not rapacious against other birds. They partake perhaps fully more of the vulture than of the eagle, and the larger refuse of the sea, the dead bodies of seals and whales, and all other unclean things which float upon the ocean, are food for the skuas.

The generic characters are: the bill of mean length, stout, hard, cylindrical, with sharp cutting edges, compressed, curved, and hooked at the tip; the base of the upper mandible covered with a cere, as in the birds of prey; but the lower mandible with a salient angle at the middle of its length, as in the gulls; the nostrils situated near the point of the bill, diagonal, straight, and partially closed with membrane; the tarsi small, and the legs naked to some distance above the knee; the toes three to the front and one to the rear, the former completely webbed, the latter almost entirely free, and all the four furnished with large and long crooked claws, the hind toe much smaller than the other three; the tail slightly rounded, and with the two middle feathers rather longer than the rest; the wings of mean length, and the first quill the longest in the wing; the body very compact and robust, much more so than that of any other sea bird, and the colours, in some of the species at least, partaking of the reddish and blackish browns which are so prevalent in land birds of prey.

The most remarkable character of the skuas is the habit from which they have obtained the name of *Lestris*, and which has been very properly substituted for the old name of *Stercorarius*. The last of these was given from the foolish belief that these birds fed upon the "mutings" of other sea birds, especially the gulls, whereas it is the food from the stomach, and not the refuse after the purposes of the other bird have been served, which is the object of the *Lestris*. They must be considered as birds of prey as well as the land *Accipitres*; but there is this difference between them, that while land accipitres are invariably murderers, the skuas are simply robbers; and, less daring, as one would say, than the others as well as less bloody, they do not hesitate to join the more cowardly craft of stealing with the more daring one of open robbery. The flight of these birds is by no means so gliding and apparently easy as that of the gulls, although even then it has an appearance of more power about it. The gull glides away, with soft wing, as if it were a mere passenger upon its organs of flight. The skua bounds and bounces with a jerking and uneven flight, as if it had other work to do in the air besides locomotion; and it has other work there, for the air is the scene of its robberies. It is no unamusing sight to observe the gulls and skuas, especially in the currents among the northern islands, where herrings and the fry of fishes are caught in the turbulent water, and brought near the surface in great numbers. The gulls whiten the air with their numbers, make the whole concave of heaven ring with their wailing cries, and plunging down catch fish after fish with great rapidity and apparent ease. The

darker coloured skuas are in the meantime hovering about, keeping a steady eye upon such of the gulls as have been successful in their fishing; but keeping the upper part of the sky, and not themselves condescending to come down for the purpose of capturing a single fish. They leave this part of the business to the gulls; and when a gull has got its load, for it can swallow a considerable quantity, and rises to the upper part with heavier flight than usual, in order to bear off the produce of its industry to its mate or its brood, the war cry of the skua is soon heard and immediately it dashes at the gull, repeating again its summons to "stand and deliver." If the summons is not answered the skua strikes at the gull, and most likely tumbles it headlong by the force of the stroke, though without doing it any mortal or material injury. But this seldom happens, for the terror of the gull makes it discharge the contents of its stomach the moment that the skua comes driving at it; and the instant that this is done the skua leaves the gull, and plunging down with great rapidity catches the prize before it reaches the water. This habit of taking the prey from the preyer is not wholly confined to the skuas; at least the American ornithologists describe the whiteheaded eagle of that country as hovering about and treating the osprey in this manner, not making the osprey disgorge the morsel which it has swallowed, but compelling it to drop the fish which it is bearing off in its talons. It seems that this habit, whether it belongs to eagle or to skua, requires as much courage on the part of the bird practising it as the habit of attacking birds in order to kill them. Indeed it requires more, for most of the birds of prey have some particular art or stratagem by means of which they come upon their prey, and despatch it without giving it time to defend itself; and it is well known that when another bird can stand upon the defensive a bird of prey will sneak off in a cowardly manner. Thus, however fond the common kite is of chickens, it dares not approach a brood hen; and even the golden eagle itself, if it ventures to stoop at a raven, turns craven and is off if it once perceives that the eye of the raven is upon it. Hence it should seem that it requires greater courage in a bird to become a robber than a murderer, and accordingly the more powerful skuas are among the most daring and courageous of the feathered race, and may be said to be in their own localities the monarchs of the sky.

There are several species of this genus, some of which generally, and others occasionally, visit the northern isles, and some of the remote coasts of Scotland; and stragglers also occasionally find their way to the English shores, especially at those times when pilchards, sprats, and other small fishes, are shoaling near the land. Their chief places, however, are those at which the gulls congregate in the greatest numbers; though even at these places, the skuas have their peculiar nesting grounds, and mix with the gulls only when the latter are engaged in fishing.

COMMON SKUA (*L. catarractes*). This is the largest species of the genus, and the one which is most abundant and best known upon the British shores. It is a large and powerful bird, not much inferior to the eagles in size and strength. The length is about two feet or upwards, the neck is short and strong, and the whole body has a firm appearance. The extent of the wings is between four and five feet, and the weight of the bird is about three pounds. The basal part of the bill has the form of that of the gulls, only

the cere reaches as far as the nostrils ; and the portion to the front of these is very hard and strong, resembling in shape the tip of the bill of a hawk or eagle. It should seem that the cere has something to do with the production of a bill of more than ordinary strength, and firmness of substance, at least all bills which are furnished with regular ceres, have those properties in a higher degree than those which are not so furnished.

The whole upper part of this bird is deep brown, with dull rust colour on the margins of the feathers, by means of which each feather is distinctly made out, something similar to what is the case in birds of prey. The colour on the under part is the same but lighter ; and the head and throat are marked with streaks of greyish ash. The tips of the secondary quills, and the bases and shafts of the tail-feathers, are white, but the remainder of these feathers are deep brown. The tarsi and toes are covered with black scales, which are placed shield-wise rather than articulated ; the claws are large and crooked, especially those on the inner toes.

These birds are natives of the high latitudes of both hemispheres, though we believe the only part of the south where they have been met with is on the islands to the southward of America. In the north they are pretty generally distributed, though they are rarely seen to the southward of the Orkney islands, and are not very common even there. They are more abundant in Shetland, and still more so on the coast of Norway, in the Faroe islands and in Iceland. Where they associate in numbers they commit great depredations on the nests of the bank-building birds, and are sometimes accused of attacking the birds themselves. Indeed in Orkney and Shetland, where they are called sea eagles, and various other formidable names, they are accused of attacking lambs. It may be that they attack those animals ; and they no doubt feed very readily upon the dead carcases of such as perish in the pastures ; but that a skua can carry off any thing in its claws, strong and crooked as they are, is impossible, because those claws have nothing against which they can act, the hind one being too small and feeble for this purpose ; and in birds which carry their prey with the feet, the hind toe and claw are always strong, and when the foot is more exclusively a carrying than a killing foot, the outer front toe is reversible. The tarsi and feet altogether of the skua are too feeble for enabling it to use its crooked claws in any very offensive manner ; and the muscles with which the thighs and legs are furnished are comparatively trifling, the strength of the bird is in the wings and the neck ; and the most obvious use of the crooked claws is that of enabling it to hold on upon the oily and slippery carcases of dead whales and other carrion, upon which it feeds voraciously.

We believe there is no well authenticated instance of a skua attacking any large and living bird, or other animal, for the purpose of making a meal of it ; and indeed its bill is not adapted for cutting or tearing recent flesh. Hence the most rational theory of its economy in the north is that which regards it as a protector of the flocks and not a destroyer. There is no question that the eagles and falcons, and occasionally the larger owls, of those remote islands prey upon the young and the diseased of the sheep ; but if the skuas take up their nesting place in the neighbourhood (and they are social in their breeding places),

those predatory birds dare not appear within some distance. The skuas breed in the moor rather than the marsh ; and some of them are on the alert at all times, ready to give notice of the appearance of an enemy. No sooner is the signal of danger given, than it is answered by the sound of a hundred wings ; and the skuas instantly surround the intruder, and drive at him on all sides. There is a warfare for which birds of prey are not prepared ; and indeed birds of prey are no soldiers : the skuas shoot themselves like javelins at the enemy, and from their weight, the strength of their make, the firmness of their bill, and the rapidity of their flight, a single stroke taking effect would finish an eagle. Even man himself does not invade the habitations of those birds without danger, because they assail him as readily as any other enemy ; and it is customary to guard against them by a sharp-pointed stick, or one with an iron spike rising above the head, upon which the birds are said sometimes to descend and transfix themselves.

Though these birds assemble in considerable numbers upon the breeding grounds, they are understood to be also always in pairs ; and when the young are full grown, and begin to disperse themselves over the ocean, it is understood that they also take their departure in pairs. Not the skuas only, but also the common gulls, and most sea birds which crowd to the rocks, the marshes, and the moors during the breeding time, disperse themselves over the sea toward the close of summer, and many of them go to considerable distances. It has often been a matter of speculation where or how they procure food on those long marine journeys ; but there is, altogether independent of the fishes, a harvest of the sea at that particular season, and a harvest arising from the birds themselves ; so that at this season the birds so far imitate their neighbours under the water, the fishes, that they "enjoy themselves in eating one another," with only this difference, that these fishes eat live fish, whereas the birds eat dead birds. It will be recollected that the whole year's brood of terns, petrels, and all other long-winged birds, disperse themselves over the sea at this season of the year, and that very many of them do so before they have acquired the average strength of their species. Multitudes of these become exhausted, tumble into the water, die there, and supply food for the rest ; and the common skua, being the most powerful and the most daring of the sea birds, of course comes in for the lion's share.

POMARINE SKUA (*L. pomarinus*). This species is the next in size and power to the common skua, and it is a more northerly inhabitant. As a British bird it is only a straggler ; but it straggles into the southern parts of the country as well as the northern. In the winter of 1831, a live specimen was sent to the Zoological Society of London from Devonshire, where it was taken, very much exhausted, apparently with the fatigue of a long journey. The upper parts of this species are of a uniform deep brown ; the feathers of the nape are long and pointed, like those on the necks of the eagles, and they are bordered with a bright yellow. The throat, the hind part of the neck and the belly are white ; there is a large band of brown spots on the breast, and similar spots on the flanks and under tail-coverts ; the bill is of an olive colour, with a black tip ; the irides are yellowish, and the feet black. The length of the bird is about seventeen inches ; but the two middle feathers of the tail,

which are slender and pointed, extend about three inches more. These are the colours of the mature bird. After the second month the whole plumage on the upper part is brown; the produced feathers on the neck brownish yellow; and those in the tail considerably shorter than in the mature bird. In the first plumage the head and nape are dull brown, with lighter brown borders to the feathers; there is a black patch in front of the eyes; the back, the scapulars, and the wing-coverts are brown, bordered with deep russet and striated dark lines; the breast, the belly, and the flanks are brownish ash, marked with zig-zags of russet; the vent, rump and tail-coverts are marked with large bands of russet and dusky; the bill is greenish blue, with the point black; the feet are bluish ash, with black webs; and the middle feathers of the tail are not above half an inch longer than the others.

The proper home of this species is the seas of North America; but the fact of its being found in Britain, however rarely, shows that it is a bird of very powerful wing, and discursive in its habits. In its general manners it resembles the common skua, but it is a less powerful bird, and therefore does not so readily attack the larger gulls. It is, however, a bird of more light and elegant form, and, if not more rapid in short flight, at least capable of remaining longer on the wing, and thus ranging farther seaward. The smaller gulls and the terns seem to be the birds which it principally attacks; and there is no doubt that the specimens which straggle to the European shores overfly themselves in their pursuit of these, and thus are unable to return to their native localities. This skua appears to stand in nearly the same relation to the common skua as the more powerful falcons stand in to the eagles; and in its plumage, and the form of its body, though not in its bill and its feet, it bears no inconsiderable resemblance to those falcons. Nor is it unworthy of remark and inquiry into the relations, that there should be a correspondence between the different species of those sea-birds which are unquestionably the most bold and predacious in their way, and the most bold and predacious of the land birds. This is one point upon which the analogy of the sea and the land might be studied to very considerable advantage; and the result of such a study would be the discovery of how far those two great divisions of the earth's surface tell upon each other, through the medium of the air, in so far as animal life is concerned.

RICHARDSON'S SKUA (*L. Richardsonii*). This species is, next to the common skua, the best known in the British seas of all the genus, and, indeed, it is found farther to the south than that one. As has been the case with many of our sea-birds, there have been very considerable mistakes and blunders concerning this one. It is the arctic gull of many describers, and the arctic skua of some who approximate to a little more accuracy, but still it is not, in reality, either the one or the other. It resembles the common gulls more than either of the former species, having the plumage less decided, and altogether less of a hawk-like appearance. The head is blackish brown, with the dark colour extending on the cheek a little below the eyes; the general colour of the upper part is brown, not so deep as in the larger skuas, and with a trace of ash-colour in it; the sides of the neck are buff; the throat, and all the under part, white, but gradually passing into greyish ash-

colour toward the vent-feathers; the bill is bluish ash, with the cere whitish, and the feet are the same colour as the bill; the webs are much larger than in the two former species, and the whole character of the bird is more that of a swimmer; the wings are very long, and the two middle feathers of the tail are still farther produced than in the pomarine skua; the entire length of the bird, tail and all, is one foot nine inches, but the nine inches are occupied by the tail, and three of these by the produced feathers in the middle. The young of these birds are of a brown colour, and have the tail-feathers much shorter than the mature ones. As has been said, they are not rare on the northern shores of Britain, and they extend as far to the southward as those of Yorkshire. They come to the British shores in April or May, along with the terns and the smaller gulls, upon which chiefly they levy their contributions. They are understood to pair for life; and they breed in this country, taking their departure in August or September, when the other sea-birds break up their summer encampments. They are not so exclusively sea-birds as the common skuas, but occasionally range inland, feeding upon worms, molluscous animals, and other small productions of the land. On the shores, however, they are very much given to plundering the smaller gulls, which they do with as much vigour and success as their more powerful congeners plunder the large ones. They are very plentiful in the western islands, where they make their nests in bogs and marshes, concealing them in tufts of herbage. The eggs are described as being only two in number, ash-coloured in the ground, and mottled with black. Altogether, these are very interesting birds, not only as they are the most abundant British species, but as they combine, to a certain extent, the appearances and the habits both of the skuas and the gulls.

ARCTIC SKUA (*L. parasiticus*). This is the species with which the preceding one has been confounded, and the description of the one has been so blended with that of the other, as to occasion no little confusion. This one does breed occasionally in some of the remoter parts of the British islands, but it is rare compared with the former. It is by much the lightest and most handsome bird of the whole genus, and is at the same time the smallest. Its length is about the same as the last, but the tail is in this one twelve inches in length, leaving only nine for the body, and the bird is not above one-third of the weight. The head is furnished with a cap of dark blackish brown, which does not reach below the eyes; the general colour on the upper part is clear brownish ash, the quills and tail-feathers being darker; all the under parts, together with the region of the eyes, the neck, and the breast, are white, but waved with ash-colour on the flanks; the two produced feathers of the tail are sometimes five or six inches longer than the rest, and they are remarkably slender and pointed, which gives the tail a very peculiar appearance. This lengthening of the tail-feathers gives the birds something the appearance of terns when they are on the wing; and, as the wings themselves are very much pointed, as well as very long, they can sport about in the air with all the activity and evolutions of the swallow tribe. They are indeed the swiftest fliers in all the genus, and their rapidity of motion makes up in some measure for their inferior strength. They never venture to attack the larger gulls, but they are very vigilant in levying their imposts on the smaller

ones and the terns; and, as the smaller gulls, and especially the terns, are more rapid fliers than the large gulls, the arctic skuas are more rapid in proportion. Their proper localities are more northerly than those of the species with which they have been confounded, and, generally speaking, they do not come so far inland. They are birds of pleasing colours, handsome form, and rapid flight, and, altogether, they possess no inconsiderable degree of interest. Indeed, though the skuas have been most unjustly accused of being fouler feeders than any other of the feathered race, there are perhaps no birds better defined as a genus, more characteristic of the localities which they frequent, and, altogether, more interesting to the student of nature. Majestic as the sea is in its own phenomena, and restless as are its waters, the sea would lose much of its interest, were it not for the countless myriads of birds which sport over its surface, and feed upon its produce. Any one who has visited a favourite resort of sea-birds, while they were there, and again after they had quitted, and spread themselves over the ocean, can tell how desolate those places are, notwithstanding their majesty as a part of nature in repose, when they are without their gulls and their skuas.

**GULO**—Glutton. A genus of mammalia, belonging to Cuvier's great order, *Carnassier*, or those which feed upon animal substances, and to the third division of that order, *Carnivora*, or those which are more or less in the habit of killing warm-blooded animals for the purpose of feeding on their flesh. Of carnivorous animals, all the genus *Gulo* belong to the plantigrade division, or those which walk on the entire length of the tarsus, or sole of the foot. Animals which have this structure, have of course the command of one joint less of the leg in the air, than those which walk on the toes; and, therefore, their walking march is much slower: generally speaking, too, they are lower on the legs, and from applying the whole length of the legs to the ground, they seem lower than they are in reality. These circumstances are, however, attended with a firmness upon the legs in those animals, which is perhaps peculiar to them; and many of them have the spine very long and elastic, so that they combine the motion of a leaping animal with the action of the spine of a snake, and thus advance with far greater celerity than from their apparently short legs one would be apt to suppose. See *PLANTIGRADE*.

Zoologists have sometimes been at a loss in what part of the system to class the animals composing the genus *gulo*. Some have arranged them with the weasel tribe, others with the bears, and others again with the badgers; but though they have some characters in common with the bears, and also with the badgers, they are clearly separated from the weasel family, because that family are digitigrade, or walk on the toes, and are consequently far swifter in their movements than animals of the genus *gulo*: Cuvier places them, and we think with great judgment, the very last of the plantigrade division, by which means they are brought next to the martens, with which the digitigrade division begins; and in this arrangement they immediately follow the badgers. This genus, in so far as we are acquainted with it, for the habits of some of the species are not a little obscure, and they all dwell in wild places, remote from the habitations of men, and live in comparative concealment, may be said to partake a little of the form of the badger, and of the disposition of the martens; for they are

certainly the most decidedly carnivorous of all the plantigrade animals.

Their generic characters are: three false grinders in each side of the upper jaw, and four in each side of the under, situated in front of one carnivorous tooth, which has very trenchant points, and is well made out. Behind this there is only one small tuberculated tooth in each side of each jaw. This is exactly the mouth of the martens; and it indicates as great a power of tearing flesh, and as little adaptation for living upon insects or vegetable matter, as is to be found in the whole order of carnivorous animals.

Notwithstanding this carnivorous disposition (for in wild animals, that is, in animals in a state of nature, "As is the structure so is the habit," is a maxim which never fails), these animals seem dull and heavy, especially in their motions; and though many of them can, by the help of their flexible spine, leap a considerable way, there is none of them that can pursue its prey successfully in regular chase. They are generally animals with a large head, and the jaws not greatly produced, so that they are remarkable rather for holding on by the staunchness of their bite, than for giving a powerful snap, as is done by long-muzzled animals. The ears of this genus are, in general, but little developed, which leads to the conclusion that they find their prey by the sight and not by hearing. The tail is short in the more characteristic species, but longer in some of the others; and instead of the pouch under the tail, which in the badger secretes so offensive an odour, they have a simple fold of the skin. All their feet are furnished with five toes, and those toes in general with strong, crooked, and sharp-pointed claws. Those claws are not decidedly prehensile, like the claws of the cat tribe; but still some species at least can readily climb trees by means of them, and also keep their hold upon the backs of their larger prey, in the same manner as is done by lions and other members of the cat family. It is to be understood when we speak of a plantigrade animal, that the expression applies more particularly to the hind feet, or at all events, that the elbow joint in the fore-feet acts in the same manner as the tarsal joint in the hind ones, and that thus, though such animals as the genus *gulo* are ungainly walkers, the whole of the hind legs come well into play when they leap. These animals are remarkable for the fineness and the thickness of their fur; and some of them have, in respect of colour, a different arrangement from almost every known species, not only of mammalia, but of warm-blooded animals generally. Their colours are very often much darker on the under part than on the upper, whereas in every other case of difference in the colour, of the two the upper part is invariably the darker. This remark applies, of course, to the unbroken colours in a state of nature, and not to those variations which take place in domestic animals. There are several species of this genus, some of which occur in both continents, and some only in one, some in the extreme polar latitudes, and some in tropical countries, and there are instances in which the number of false grinders differs from the typical number above stated, and where the food also varies from that of the more typical species; but the characteristic ones are inhabitants of the north, both of the eastern continent and of America.

**COMMON GLUTTON** (*G. vulgaris*). In this species the length from the nose to the tail is about twenty-

eight inches, and from the trunk of the tail about seven inches and a half. The tail has a covering of long and thick hairs, which are of a reddish colour, having a black tip. The hairs on the back, head, and belly, are of the same colours, but of a much finer and softer texture. The throat is whitish, marked with black. Along the sides, from the shoulder to the tail, is a broad band of ferruginous hue. It is to be observed, however, that the animal varies considerably in colour; and in consequence of this variation they have been multiplied into several species, or at all events several varieties. Generally speaking, those which inhabit the close forests are darker in the colours than those which inhabit more open places; and this is what one would naturally be led to expect from the fact that the upper part, which is most exposed to the light, is generally paler than the under. It seems also that in America they are upon the whole paler in the colours than in Europe. This may arise from the American forests not being in general so close as those of northern Europe. But in America they vary considerably, and there is little doubt that the paler ones, which are known and described under the name of *Wolverine*, are nothing more than coloured varieties, to which the name of a very ridiculous imaginary animal, invented by the heralds, has been applied.

The common glutton is an inhabitant of all the arctic regions, Scandinavia, Canada, the northern parts of the United States, and, probably, Siberia, and the central and western parts of polar America. But though an animal of the extreme north, and unknown in any country considered as temperate, it does not hibernate, but is on the alert, and feeds as rapaciously during the winter as at any other time.

The name glutton was originally applied to this species in consequence of the voracity of its appetite; and though the old accounts of it are very greatly, and even ludicrously, exaggerated, yet there is no question that it can eat more, and probably more frequently, than any other animal of its size. The old stories went so far as to say that it sometimes gorged itself until not the stomach, but the external skin actually split open; and that, to prevent this catastrophe, it used to rub itself between two close growing trees, and thereby both promote digestion, and also get rid of the superabundant part of the food. This, of course, is highly absurd; because there is no animal in a state of nature which takes its natural food to a single ounce or atom beyond the quantity at which that food ceases to be wholesome; and though man, acting upon his own fallible propensities, and not upon the pure instinct of nature, may sometimes die of surfeit, this is a case which is quite unknown among the other animals. It is true that many of those species which, from their own peculiar nature and that of their food, are subjected to long periods of abstinence, fall into a state of stupor after a hearty meal; but this is not disease; and though the animal is thereby rendered incapable of active exertion for a time, it suffers no injury. In fact, after it has fed heartily it has no use for exertion until it is again hungry; and therefore it is a wise provision of nature that it should at those times remain still, and not alarm those animals upon which it feeds, and of which it is not the destroyer but the regulator.

The glutton is scarcely capable of catching any animal by pursuit, and therefore its habits are those of a liar in wait. Small mammalia and birds are under-

stood to be its ordinary fare; but in cases of emergency, it can prey upon larger animals, upon the different species of arctic deer, and even on the reindeer itself. Indeed, from its mode of attack, the size and strength of its prey do not appear to be matters of very material consequence. The glutton is, as we have said, well adapted for climbing trees, and its length and lowness, the extent of its feet, and the sharpness of its claws, enable it to hold on upon a branch, crouching so that it is not easily seen. The deer and other animals usually have tracts or passages through the thick parts of the wild forest; and so prone are all animals which feed on vegetables to follow in each other's footsteps, that sheep, horses, and rabbits, and even mice, are road makers, although the surface upon which they make the road, by successively following each other, may be quite level and uniform. The same instinct which leads the glutton to prey upon those animals leads it to the track along which they pass; and, getting into a branch which overhangs this track, it drops down on the shoulders of the passing animal, where it keeps a firm hold with its sharp claws, tearing and lacerating all the while with its very formidable teeth, at that part where the neck joins the shoulders. The pain produced induces the animal to set off at great speed, and the excitement increases the discharge of blood from the wounded part, so that, as is the case with the larger prey of the lion, the strength and fleetness of the animal contribute to its destruction; and the glutton continues in its place of attack until the prey tumbles down completely exhausted, and incapable of making any farther resistance.

But notwithstanding the voracity of this animal, and the stratagems to which it has recourse to compensate its want of swiftness, the glutton is capable of being tamed; and instances are mentioned in which, when properly fed, it has shown not only no disposition to ferocity, but seemed grateful for the food given it and the attention paid it. We might expect this; for there is no animal more ferocious than the dog, even in a semi-barbarous state. A tame one, which was kept at Dresden, and exhibited as a performer of tricks, would eat thirteen pounds of flesh in a day without appearing to be satisfied. That which Bufon possessed, on the contrary, consumed only four pounds of meat daily; and another, which belonged to the Hudson's Bay Company, was contented with the ordinary allowance of a mastiff dog. This is the only species, at least the only well made out one, which is met with in the arctic countries.

*GRISON (G. vittatus).* This animal is a little larger than the European weasel; and it is the one which is most remarkable for light colour on the upper, and dark on the under side of the body. The upper part of the body and tail are covered with hair alternately annulated with black and white, but which, from the mixture, produce a grey appearance, much in the same way as grey is produced in the badgers. The whole of the under part of the body and the inside of the legs are black. A white line on each side of the head passes above the eye to the ear, below which the head is black, but above it is white. The ears, which are of a white colour, are very small, and have no produced lobe; the tongue is rough; the pupils of the eyes are round, indicating a day preyer; and the sides of the mouth are furnished with small mustachios. The fur is of two sorts, one short and woolly, and concealed among the roots of the long silky hair,

which last gives the animal its colours, as above stated. The toes are large, and half way united by membranes. The tail, which is one-third the length of the body, is borne horizontally. The animal conceals itself in holes, and when attacked gives out a strong and most offensive smell. This proceeds from a fluid like honey, secreted by two glands near the anus; and the possession of these is of itself perhaps enough for a specific and even a generic distinction.

It is found only in South America; and the names of different European animals have been, not very judiciously, applied to it by different authors. D'Azzara calls it the "little ferret;" Buffon, the "Guiana pole-cat;" and Thunberg, the "Brazilian bear;"—all of which names are liable to mislead. It is exceedingly ferocious in a state of nature, a very hearty feeder withal, and as it is quick in its motions, that is, on the alert and can leap well, it commits great depredations upon the smaller mammalia and the birds of that country which it inhabits. Its distribution throughout South America is very general, and it is far from rare in any country. It can be tamed; and if properly fed its manners are gentle, but if it is allowed to become hungry it does not hesitate to attack any animal which it can master that comes within its reach. One which was in the possession of M. F. Cuvier had been tamed—at least, to a certain degree. It did not appear to distinguish one person from another, was very fond of play, and for that purpose all comers were alike to it. It seemed to derive pleasure from being stroked down the back with the hand. When invited to play, it would turn over, return with its paws the caresses addressed to it, bite gently the fingers it could seize, but never so as to hurt or wound them. One might almost have imagined that it felt the degree of resistance which the skin was capable of making, and proportioned the force of its bite accordingly, when it meant only to express its joy. It knew the fingers of a person without seeing them. Notwithstanding, this animal preserved its ferocity for all those living beings that could become its prey. Even when satiated with food, it testified, in a lively manner, the desire of getting possession of such animals. One day it broke the bars of its cage to attack an animal that was within reach, which it mortally wounded. When it could catch a bird it killed it directly, and kept it by for provision, as was its custom to do with the meat it received, after having satisfied its appetite.

**TAÏRA** (*G. barbarus*). This animal inhabits the same countries with the grison, which it resembles in manners but is larger in size. It is found not only in the South American continent, but also in the West Indian islands, where it is called the greater weasel. The general fur all over the body is black, or brownish black; but the head and neck are often more or less grey, and there is a large patch of white on the throat and fore part of the neck. The ears are very short and white; the length, exclusive of the tail, is about two feet; and the tail, which is covered with longer hair near the body, is about fifteen inches in length. The feet have five toes each, and the form is rather peculiar. The middle toe and the one on each side of it are united together as far as the claws, while the outer and inner ones, which are very short, are detached at the articulation of the others. This animal, as it is more powerful, is described as being proportionably more predatory than the grison. Like that it is a burrowing animal, and as it lives in a state of

still greater concealment than its congener, its manners are not much known. From the following notice in the proceedings of the Zoological Society's Scientific Committee, May 31, it should seem that there are at least several coloured varieties of this animal, if not several distinct species, to be met with in South America. "A living individual," says the report, "apparently referable to the *Gulo barbarus*, Linnæus, was exhibited. It was presented to the Society by Edmonstone Hodgkinson, Esq., of Trinidad, who describes it as being 'playful and gentle, although easily excited, and very voracious. It is exceedingly strong, as is indicated by its shape, and it has the same antipathy to water as a cat.'" Mr. Hodgkinson suspects that it is a native of Peru. He obtained it in Venezuela, where it was presented to him by the president, General Paez. The name he received with it was "the *Guache*;" but this appellation, it was observed by Mr. Bennet, was probably erroneously applied to the present animal, belonging rather to the *Coati*, the orthography of which is variously given, as *Coati*, *Conati*, *Quasje*, *Quachi*, and *Guachi*. The latter term occurs in the "Personal Narrative" of the Baron Von Humboldt, where it evidently refers to a nocturnal species of *Nasua*.

The form and general appearance of the animal were remarked to be altogether those of a *Mustela*, to which genus it is probable that it should be referred, together with the typical *Gulo barbarus*. A specimen of the latter was placed on the table, from which the living animal was shown to differ, by the absence of the large yellow spot beneath the neck: a remarkable distinction in this group, but on the occurrence of which, unless confirmed by several specimens, it was considered improper to propose regarding it as a distinct species.

**ORIENTAL GLUTTON** (*G. Orientalis*) is a native of the mountains of Java, and probably also of other parts of the East. It was first noticed by Dr. Horsfield, but does not appear to be by any means uncommon in that country. The natives call it *Nyentek*. In size it is rather smaller than the pole-cat of Europe, and it is much more slender in the body than the glutton. The fur is thick, consisting of long hairs, closely arranged, silky at the base, of a brown colour, and somewhat glossy, slightly tinged with reddish brown. In some lights it appears diversified with a greyish and tawny colour. This fur covers almost the entire body and head, and the whole of the tail and extremities. The sides of the head, neck, throat, breast, and a broad patch on the top of the head, which passes gradually, decreasing in breadth, to the middle of the back, are white, with an obscure tint of cream colour, of different degrees of intensity. This colour, also, exists less distinctly in a longitudinal band, along the lowest part of the abdomen. The tail is almost half the length of the body, is somewhat bushy, and terminated with bristly hairs.

There are several other species understood to be natives of the East, of which specimens and drawings have been brought to Europe; and in some of them the animals themselves have been obtained in the live state. Modern naturalists are inclined to refer both the Oriental and South American ones to a different genera from the glutton of the Arctic regions; but as they appear not to have made up their minds exactly with regard to the genera to which the different species should be referred, or how many of them should be made what is technically called the types of new genera, those matters of arrangement cannot be rep-

dered very interesting to the general reader. That there are many carnivorous animals in the tropical forests belonging to the plantigrade division of which we have no good account, and of many of which we have yet no account at all, there seems little reason to doubt; and from the extent of those forests and their tangled nature, interlaced as they are with climbing plants, and crowded with prickly ones, the exploring of even a portion of them is attended with much difficulty, and no little danger. But the vast quantity of food for such animals which those forests afford, and the general law of nature that there is always some proportion between the quantity of prey and the numbers of the preys, necessarily leads to the conclusion which we have stated. It is probable that these animals do not exactly take up the character of our badgers and continue it to the character of our martens, as the title of glutton is supposed to do in the north; because we must no more suppose that the succession of beings in a tropical climate must follow the gradation which it does in ours, than we must consider the tropical animal as having an individual type in our climates. From all that we know in the meantime, it is not improbable but that the animals in question may form a sort of gradation from the *Ailurus* (see that article), which has the claws partially retractile, to the *Paradoxurus*, of which some account will be found in its place in the alphabet. Indeed, there is a disposition to refer those Oriental animals which have hitherto been regarded as gluttons to the genus last mentioned; but much more information is required before this portion of the animal kingdom can be so well known as that we shall be warranted in speaking positively concerning it. One of the animals, once referred to the genus *Gulo*, and now to *Paradoxurus*, is,

**THE MASKED GLUTTON (*G. larvatus*).** This one is from the east, but what particular locality is not exactly known, although it is somewhere either in India or the eastern islands. It is larger and stronger than the European polecat; olive brown and grey in the general colour, but with the tip of the tail and the extremities of the feet black. The general colour of the head is black, but there is a large white streak from the forehead to the nose, some mottlings on the cheeks, and a paler band round the throat from the one ear to the other. The head of this one resembles not a little the dasyurus of Australia, and the body and tail have some resemblance to those of a cat. The essential characters are, however, different from either of these animals.

**THE RATEL (*G. mellivora*)** is found in Southern Africa, but it is also a native of India. It is about two feet in length from the nose to the tail, and the tail is about eight inches long. The body is marked by a broad ash-coloured stripe, which extends from the forehead the whole way to the tail, and at each side of this there is a grey stripe which separates the ash-colour from the black on the under part of the body. According to the accounts, this animal does not live so much upon other animals as upon honey, which it obtains by attacking the nests of the wild bees, and in this, it is said, they make use of another animal, which acts as a guide. Towards sunset it is particularly attentive in watching the motions of these industrious insects, following with great care the direction in which they fly. In its predatory range it is not unfrequently assisted by the *Cuculus indicator*, a bird which excites its attention by a loud grating cry, flying at the same time slowly forward to the

place where a swarm of bees have taken up their abode. The ratel follows the sound with great attention, and, having plundered the nest, leaves enough behind as a reward for the services of its guide. Owing to the toughness of its skin, it has little to dread from the stings of the insulted bees. The nests, however, which are built on trees, are beyond its reach. In the first transports of its rage it gnaws and bites the trunk, and these bites are sure marks for the inhabitants that a bees' nest is to be found there. Such is the account given of this animal in Southern Africa; and we shall add that given of it by General Hardwicke as a native of India. "The claws," says the General, "are unequal, those of the fore feet very long and awl-shaped, the three middle ones much longer than the two lateral; the interior toe very remote from the rest; the claws of the hind toes remarkably short, nearly equal, and bearing no comparison to the strength of the fore feet."

"This animal is found in several parts of India along the courses of the Ganges and the Jumna, in the high banks, which in many parts border these rivers. It is rarely seen by day, but at night visits the neighbouring towns and villages inhabited by Mohammedans, and scratches up the recently buried bodies of the dead, unless they are quickly covered with thorny bushes."

"The natives, when encouraged by the expectation of purchasers, dig the animals out of their subterranean retreats, and take them alive. The full-grown ones are with difficulty secured, and seldom bear confinement long, but roll and beat themselves about till they die. When taken young, they are very manageable, docile, and playful. It is a bold animal, its hide remarkably thick, and its strength too much for most dogs of common size. Its general food is flesh in any state, but it is remarkably eager after birds, and living rats seem almost equally acceptable. It has an inclination to climb upon walls, hedges, and trees. This, however, it seems to execute clumsily, but seldom falls, and will ramble securely upon every arm of a branching tree that proves strong enough to bear its weight without much motion. This species burrows with great facility, scratching the earth like a dog with the fore feet, and expelling the loosened soil to the distance of two or three yards backward. In ten minutes it will work itself under cover, even in the hardest ground, and is restless till it can form such a retreat to sleep in. It sleeps much by day, is watchful during the night, discovering inquietude by a hoarse call or bark proceeding from the throat. The hair is short and wiry, nor has it any of the softness of fur. It is known to the natives of Hindostan by the name *Bajoo*."

Other species of smaller dimensions, and found in various tropical climates, have been mentioned by different authors. The illustrious Humboldt, for instance, mentions one which he observed in the Andes, and to which he gave the name of *Gulo Quitsensis*. It is of small size, black in the colour, with a white band along each side, and the tail marked with white and black. There are also several other species, among which we may mention one of very peculiar shape, and of a chestnut colour, which was preserved in the late Bullock's Museum. This one measured about two feet three inches in the length of the head and body, and a foot and a half in the tail, which was very bushy. The body was long and lanky, but the legs were very stout, and the

claws large and very much crooked. Altogether, its appearance was peculiar, though abundantly expressive of ferocity, but where it came from was unknown; and we have not heard that any living specimen has been seen. There have also been found, in some of those ancient charnel-houses of Europe which contain the bones, or partly the bones, of animals not now found in that quarter of the world, along with those of others which are extinct everywhere, certain bones which have been referred to the gluttons, and from which one might conclude that, at some period of European history, they were much more plentiful in species and in individuals than they are now; and there seems to be some sort of evidence of this in the fact of their remnant being driven, as it were, to the verge of the extreme north.

On a portion of zoology that offers so many difficulties, and respecting which the accounts are so imperfect, and so much at variance with each other, it might not be wise to hazard any very positive conclusion. But, from all the evidence, it should seem that there are three distinct families of those animals, each taking a type from a particular locality, and differing entirely from the others. First, there is the northern one, consisting of only the common glutton, and its coloured varieties, at least we know of none else. Secondly, there are the South American species, which seem to partake of the general character of the mammalia of that quarter of the world, in being different from all the rest. It is possible that the typical animals to which these are allied are the genus *Mephitis* of Cuvier, which are so remarkable for the offensiveness of the smell which they give out when disturbed. Thirdly, the eastern animals, which have for their best known type the *Civets*, which are also furnished with a scented secretion, but which, to some at least, is considered agreeable. More information is wanted, however, before we can accurately arrange these extraordinary animals.

GUM ARABIC TREE is the *Acacia Arabica* of Willdenow. A native of the East Indies.

GUM CISTUS is the *Cistus ladaniferus* of Linnæus. A flowering shrub, long one of the ornaments of our gardens. It belongs to the natural order *Cistaceæ*.

GUM SUCCORY is the *Chondrilla juncea* of Linnæus. A herbaceous perennial, native of Europe, belonging to *Compositæ*.

GUM TREE is the *Eucalyptus robusta* of Smith. A timber tree indigenous in New Holland, and belonging to the natural order *Myrtaceæ*.

GUSTAVIA (Linnæus). A genus of plants named in honour of Gustavus III., king of Sweden, the patron of his learned subject Linnæus. Class and order *Diadelphia Polyandria*, and natural order *Myrtaceæ*. Generic character: calyx superior, turbinate, whole, or very obtusely toothed; petals four, six, or eight, large and ovate; stamens shorter than the petals, united at the base; anthers oblong and erect; style filiform; stigma simple; seed vessel leathery, roundish, from three to six-celled, and without valves. There is only one species described. It succeeds in our stoves, and is propagated by cuttings rooted in strong heat.

GUTTIFERÆ. A natural order containing about a dozen genera, many of which are highly interesting plants. They are trees or shrubs found in the hottest parts of the world; the leaves are opposite, leathery, entire, with short petioles, a strong midrib and often

with parallel costulæ extending to the margin, and without stipules.

The inflorescence is in general axillary and racemose, but sometimes terminal and paniculate, or crowded and lateral. The calyx is from two to six sepaled, often persistent, roundish, membranaceous, frequently irregular and coloured; petals from four to six, rarely more; stamens numerous, indefinite, and inserted below the germen; the germen is superior and free; style none or very short, and the stigma peltate and radiate with the style cleft. The fruit is dry or succulent, either baccate, capsular, or drupaceous, and one or many celled, one or many seeded. Among them is the mangosteen, considered one of the most delicious of fruits. The flowers of all the order being showy, the foliage good, and the properties interesting, every species deserves cultivation.

GYMNADENIA (Richard). A genus of hardy herbaceous plants, belonging to the natural order *Orchidææ*. They were formerly included in the genera of *orchis* and *satyrium*, by Linnæus, but separated by Richard and Sprengel. When cultivated they are kept in shady borders of bog-earth.

GYMNARCHUS. A genus of soft-finned fishes without ventral fins, belonging to the eel-shaped family, but having little resemblance to the common eels. The generic characters are, the body elongated and scaly, the gills with but little opening, as in the genus *Gymnotus*; but there is all along the back a soft rayed fin, contrary to the gymnoti, and, unlike them also, there is no fin between the vent and the tail, and the tail terminates in a point. The head is conical and without scales, the mouth small, and furnished with a single row of treacher teeth in each jaw. There is but one known species, *G. Niloticus*, which is, as its name imports, a native of the Nile, but nothing is known of its habits.

GYMNEMA (R. Brown). Climbing ornamental plants from the East Indies, formerly called *Asclepias*, *Asclepiadeæ*.

GYMNOCLADUS (Lambert). An ornamental shrub or tree, a native of Canada. It belongs to *Leguminosæ*, and is increased by cuttings of its roots.

GYMNOPLEURUS, (Illiger). A genus of coleopterous insects, belonging to the section *Pentamera*, sub-section *Lamellicornes*, and family *Scarabæidæ*; distinguished by having the body depressed, the elytra deeply notched, or sinuated, near the shoulders, the middle legs widely apart, the four posterior tibia ciliated with small spines, and the last joint of the tarsi as long as all the remainder together; the thorax has an impression on each side. The type of this genus, of which there are numerous species, is the *Ateuchus pilularius* of Fabricius, which has obtained its specific name from the curious manner in which the eggs are deposited, and which is thus described by Catesby, as observed in a North American species, known by the name of the tumble-dung beetle; like our dung beetles, *Geotrupes*, these insects bury their eggs in dung, but the latter form the mass in which they are enclosed into small balls. "I have attentively admired their industry," he proceeds, "and mutual assisting of each other in rolling their globular balls from the place where they made them to that of their interment, which is usually the distance of some yards, more or less. This they perform breech foremost, by raising their hind parts and forcing along the ball with their hind feet. Two or three of them are sometimes engaged in trundling

one ball, which, from meeting with impediments on account of the unevenness of the ground, is sometimes deserted by them. It is, however, attempted by others with success, unless it happens to roll into some deep hollow or chink, where they are constrained to leave it; but they continue their work by rolling off the next ball in their way. None of them seem to know their own balls, but an equal care for the whole appears to affect all the community. They form these pellets while the dung remains moist, and leave them to harden in the sun before they attempt to roll them. In their moving of them from place to place, both they and the balls may frequently be seen tumbling about over the little eminences that are in their way. They are not, however, easily discouraged; and by repeating their attempts, usually surmount the difficulties. They find out their subsistence by the excellence of their organs of scent, which direct them in their flight to newly fallen dung, on which they immediately go to work, tempering it with a proper mixture of earth. So intent are they always on their employment, that though handled, or otherwise interrupted, they are not to be deterred, but immediately on being freed, persist in their work without any apprehension of danger. They are said to be so extremely strong and active, as to move about, with the greatest ease, things that are many times their own weight. Dr. Burchell was supping one evening in a planter's house of North Carolina, when two of them were conveyed, without his knowledge, under the candlestick. A few blows were struck on the table, and, to his great surprise, the candlestick began to move about apparently without any agency; and his surprise was not much lessened when, on taking one of them up, he discovered that it was only a chafer which moved."

It has been the good fortune of the writer hereof to examine a living specimen of the North American species, whose habits are recorded in the above extract, and which was brought to this country from the United States, having lived during the passage without taking any food.

**GYMNOTUS** (electric eel). *Gymnotus*, literally means "naked back," and, as applied to a fish, it imports that there is no dorsal fin. The electric eel, so celebrated in natural history, is not the only species, even when the genus is cleared of some which do not belong to it; it is, however, the one which is most interesting, and therefore our attention shall be chiefly directed to it.

The characters of the genus are: the gills partly closed by a membrane, but this membrane opens in front of the pectoral fins; the vent placed far forward, so that the anal fin extends the greater part of the length of the body, and generally to the very extremity of the tail. There is no dorsal fin, and even in the gymnotus, properly so called, there is no caudal fin, though the anal fin extends under the tail to its extremity. The skin is without any perceptible scales; the intestines are much folded, and have numerous cæca. They have a double air-bladder, one branch of which extends far back into the cavity of the abdomen; the other is oval, consisting of two lobes, and lies immediately over the gullet. All the species which are known are inhabitants of the rivers and fresh water pools of South America. That which has attracted the greatest attention is

THE ELECTRIC EEL (*Gymnotus electricus*). From the singular power with which it is furnished of giving

electric shocks, often very severe, as well as from the very peculiar apparatus upon which this power appears to depend, the electric eel is not only one of the most extraordinary of fishes, but it is one of the most wonderful productions of living nature; and if it were possible to carry our physiological analysis so far as to ascertain what connexion there is between the action of life in the animal and the charging and discharging of its electric, or rather galvanic battery, it would bring us one step nearer to that mysterious relation which there unquestionably is between electric action and animal life.

This singular fish is of considerable size, being very frequently between two and three feet in length, and instances are mentioned of specimens five feet, or even six feet, in length, being found. It is a thick and heavy looking fish too, not possessed of the "lithe" form of the common eels; the body is pretty uniform in thickness throughout, though it is rather more compressed than the body of an eel; and when the length is about four feet, the circumference at the thickest point is more than fifteen inches, and the depth in the side about seven. The head is full of little vesicles, which secrete a sort of slimy matter, wherewith the body of the fish is lubricated; and similar organs, though smaller in size, are scattered over different parts of the body and tail. When we say the tail of this fish, we of course mean all that part of it which is behind the vent; for as there is no caudal fin, there is no specific tail other than this portion of the body. So copious is the discharge of this matter, that when the fish is kept alive as a curiosity, which it often is, in troughs or large tubs of water, in its native country, the water requires to be frequently changed. From the feeding of those specimens, it is ascertained that the food of this curious fish consists indiscriminately of worms and small fishes; for it eats either of these with equal avidity.

It is far from a handsome fish; and its colour is dull, being an obscure blackish green, with a few dark stripes, barely perceptible. Its tail, even in point of muscular vigour, is a most powerful instrument, and amply compensates for the deficiency of fins. In the northern parts of the South American continent it is very common, being found equally in the great rivers, the small streams, and the stagnant pools; and in those places where the water forms the only pathway, as it not unfrequently does in the wilds of those countries, this fish is a most formidable creature. The vigour of the animal, its serpent-like form, its dark appearance, and the violence with which it gives its shocks, all tend to make it an object of terror; and those who are fond of fanciful writing have endeavoured to persuade their readers that the same energy of the sun which, in those lands of extreme heat and fertility, matures the choicest fruits, and calls forth the beauty and the perfume of the finest flowers, also gives deadly strength to the boa, the most fatal poison to the bush-master, and this strange electric action to the gymnotus.

The apparatus in which evidently this power is lodged, is a very singular one, and consists of four organs, which are situated longitudinally in the tail of the fish (which, as we have said, constitutes by far the greater part of it), and those organs amount to between a half and a third of the whole volume of the tail,—indeed they occupy a full third of the whole volume of the fish. The larger organ occupies the middle of the side, and extends to the extremity of

the tail; and the two are separated from each other by the muscles of the back. The small ones are under these, and extend nearly the same length, but are altogether much smaller, and very slender toward the tail. The two smaller organs are separated from each other along the mesial line by the bones of the anal fin, and the muscles which give motion to that fin; and there are also small muscles between those small organs and the skin. The larger ones are separated from the skin, or rather united to it by loose cellular tissue only, so that upon the skin being removed they are seen at once. The organic part of this singular apparatus consists of a vast assemblage of cells, which fancy can easily conceive to have some analogy to the phials in an electric battery, or rather perhaps to the divisions of a galvanic one, for the cells are, like those divisions, filled with a liquid. The partitions of the cells consist of flat longitudinal septa, crossed by nearly similar partitions. The septa extend nearly the whole length of the fish, and have their breadth not much less than half the diameter of the body. They consist of thin and delicate membranes. These septa are, in the large organs, nearly straight and parallel to each other for the greater part of their length, and in consequence of this they are not all the same length. Neither are they at the same distance apart throughout the whole of their breadth. They are widest externally, and converge toward the interior. Whether the number is the same in large and small specimens has not been clearly ascertained; but such may be the case. In a fish two feet four inches long there were thirty-four at the broadest part, and they were nearly half an inch apart externally. In the smaller organs the septa are curved or serpentine, and much nearer each other; so that though only half an inch in breadth in the specimen alluded to, this organ contained forty. The space between every two septa appears to be a distinct organ; and these organs are divided crosswise by remarkably thin partitions, which are near to each other; so that Dr. Hunter counted two hundred and forty in an inch in length. The minute cells formed by those transverse partitions are filled with a fluid; but what the particular nature of this fluid is in the living animal, or how it acts upon the partitions, so as to produce the electric energy, has not been, and possibly cannot be ascertained. Still there is a wonderful resemblance between those organs and galvanic troughs; but the incomprehensible part of the matter is, how the animal contrives to make those troughs act. If the animal is touched with one hand only, that is, if it is touched only in one place, no shock is felt; but if it is touched at two places considerably apart from each other, the shock is very violent. Humboldt states that he felt more pain from the shock of a large gymnotus than from that of a powerful electric spark; and when he placed both feet upon one newly out of the water, at some distance from each other, he received a most violent shock, and felt pain for the rest of the day, not only in his legs, but in almost every joint of his body.

It appears, from the experiments of Dr. Williamson, Mr. Walsh, and many others, that nearly the same substances are conductors and non-conductors of the shock of the gymnotus, as are conductors and non-conductors of common electricity. It may with perfect impunity be touched with a glass rod, or with the hand wrapped up in a dry silk handkerchief; but metals, water, and all moist bodies, conduct it

readily. The shock is conveyed to a considerable distance from the animal, so that it can strike the smaller fishes dead, or, at all events, deprive them of motion at the distance of fifteen feet. One of the experiments made by Dr. Williamson is worthy of mentioning. He took a common cat-fish, which is a very vigorous fish, put it into the water, and placed his hand in the water, watching what would occur. The gymnotus swam up to the cat-fish, but, in the first instance, turned away without doing anything. It speedily came back, however, and discharged its battery at the cat. While it did so, the Doctor felt a severe shock in his fingers, and the cat turned on its belly, and remained motionless. With several other fishes the result was similar; but, though stunned, it does not appear that they were killed, or even received any permanent injury, for, when instantly put into water apart from the gymnotus, they speedily recovered. Hence it is probable that the shocks given by this fish serve only to benumb its prey until it can swim up and devour them. Instances are mentioned of fishes of this formidable genus of much greater dimensions than those to which we have alluded; and the Indians say that swimmers are often drowned by the stroke of a large gymnotus, and that the most powerful quadrupeds share the same fate.

That the shocks are voluntary on the part of the animal, that is, given or not given, according as it is disposed, is a proof that, though the electric battery is a mechanical or organic structure, the working of it is a function of life. This is farther proved by the fact, that, when these fishes have been provoked, and made to discharge their batteries repeatedly, until they are exhausted, they may be taken in the hands with little more danger than any other fish, for it appears that the electric organs take some time to recover their tone. "In America," says Humboldt, "they take advantage of this interval, and catch these fishes with but little risk. They force wild horses to enter the ponds inhabited by the electric eels. These unfortunate quadrupeds receive the first discharges; stunned and overthrown, they disappear under the water, and the fishermen take possession of their assailants either with their nets or with the harpoon. The combat is finished in about a quarter of an hour."

The water in which Humboldt saw experiments made on those eels was of a much higher temperature than the water of Europe in the open air; and Humboldt rationally concludes that the inferior temperature is the cause of the weakened power in those individuals which have been tried in Europe. The gymnotus is not the only electric fish. That power in the torpedo has been known from remote antiquity; and it is also possessed by a species of *Silurus*, by one of *Trichiurus*, and by one of *Tetraodon*. In all (notices of which will be found in their respective places), the organs appear to be substantially the same, but there appears to be none which in the power of its shocks comes nearly up to the gymnotus. The following account, by Humboldt, of the method of taking the gymnotus, is so characteristic and so well told, that we shall make no apology for laying it before our readers:—"Having," says Humboldt, "remained for three days to no purpose in the town of Calabozo, and received but a single eel, and that rather weak, we resolved to proceed to the banks of those pools in which gymnoti abound, and make our

experiments in the open air. We came first to a small village named *Rastro de Abaro*. The Indians conducted us thence to the Cano de Beru, a reservoir of miry and stagnant water, but surrounded by rich vegetation. We were greatly surprised when they informed us that they were going to catch about thirty half-wild horses in the neighbouring savannahs, to employ them in fishing for the electric eels. The idea of this sort of fishing, which they call *embarbasear coucaballas* (deadening by horses), is singular enough. The word *barbasee* signifies the root of any poisonous plant, by the contact of which a great mass of the water receives, in an instant, the power of killing, or, at least, of intoxicating and benumbing the fish. These come to the surface of the water when they have been poisoned by this means. As the horses, driven here and there through a pond or pool, produce the same effect upon the alarmed fishes, the Indians, confounding cause and effect, apply the same appellation to the two kinds of fishing. While our host was explaining to us this strange system of fishing, a troop of horses and mules arrived. The Indians had made a sort of enclosure around them, and, pressing them closely on all sides, forced them to enter the water. I shall but imperfectly depict the interesting spectacle presented to our view by the combat of the eels against the horses. The Indians, provided with very long reeds and harpoons, placed themselves around the basin. Some of them mounted upon trees, whose branches overhung the surface of the water. They all prevented, by their cries and the length of their reeds, the horses from attaining the shore. The eels, stunned and confused by the noise of the horses, defended themselves by the reiterated discharge of their electric batteries. For a long time they seemed likely to gain the victory over the horses and mules. These were seen in every direction, stunned by the frequency and force of the electric shocks, to disappear under the water. Some horses, however, rose again, and, in spite of the active vigilance of the Indians, gained the shore exhausted with fatigue, and, their limbs being benumbed by the electric commotions, they stretched themselves at full length upon the ground. I could have wished that a skilful painter had had the opportunity of seizing the moment when the scene was most animated. The groups of Indians surrounding the basin—the horses with their manes bristling, terror and anguish depicted in their eyes, trying to escape the storm which surprises them—the yellowish and livid eels, which, like huge aquatic serpents, are swimming on the surface of the water, and pursuing their enemy—all these objects presented, without doubt, the most picturesque assemblage imaginable. I remember the superb picture of a horse entering a cavern and frightened at the view of a lion. The expression of terror is not stronger there than what we witnessed in this unequal contest. In less than five minutes two horses were already drowned. The eel, more than five feet long, glides under the belly of the horse or mule; it then makes a discharge from the entire extent of its electric organ. It attacks at once the heart, the viscera, and particularly the *plexus* of the gastric nerves. It is not, therefore, surprising that the effect it produces on a large quadruped should exceed that produced upon a man whom it touches only at one of his extremities. I have my doubts, however, whether the gymnotus kills the horses immediately. I rather believe that the latter, stunned by the reitera-

tion of the electric shocks, fall into a profound lethargy. Deprived of all sensibility, they disappear under the water; the other horses and mules pass over their bodies, and they perish in a few minutes. After this commencement, I was afraid that the sport might terminate very tragically. I did not doubt that, by degrees, the greater part of the mules would be drowned. Eight francs is paid for each of them, if the master happens to be known. But the Indians assured us that the fishing would be soon at an end, and that nothing is to be dreaded but the first attack of the gymnoti. In fact, whether the galvanic energies are accumulated in repose, or the organ ceases to perform its functions, when fatigued from too long use, the eels, after a certain time, resembled discharged batteries. Their muscular motion is still equally active, but they have no longer the power of giving electric shocks. When the combat had lasted a quarter of an hour, the mules and horses were less affrighted; they no longer bristled up the mane, and the eye was less expressive of fear and suffering. They were no longer seen to fall backwards; and the eels, swimming with the body half out of the water, and now escaping from the horses instead of attacking them, began themselves, in their turn, to approach the shore." The Indians, and also the negroes, eat the flesh of those singular fishes, but it is said to be hard, flavourless, and not very nutritious. After this celebrated species, the other gymnoti can hardly bear to be mentioned.

**GYNANDROPSIS** (De Candolle). A genus of tropical herbs, belonging to the natural order *Capparidæ*, separated from *Cleome* by De Candolle.

**GYPSOPHILA** (Linnæus). A genus of annual and perennial herbs, natives of Europe. They bear decandrious flowers, and belong to the natural order *Caryophyllæ*. The smaller species do well on rock-work, and the larger have a place on flower borders. They are propagated by cuttings or seeds.

**GYRINIDÆ**. A family of coleopterous insects belonging to the section *Pentamera* and sub-section *Hydradephaga*, or water-beetles, and distinguished by the minute size of the antennæ, which are clubbed, and shorter than the head, the second joint being dilated externally into a kind of ear; the two fore legs are long, and advanced in front like arms, but the four posterior legs are very short and compressed, but broad, forming two pair of short strong oars. The eyes are four in number, two being placed above and two below; the palpi are very small; the thorax short and transverse; and the elytra oval, depressed, and obtuse at the extremity, leaving the tip of the abdomen exposed.

This family corresponds with the genus *Gyrinus* of Linnæus, and, unlike the *Dyticidæ*, to which they are nearly allied, these insects are distinguished by the metallic brilliancy of their covering; living for the most part upon the surface of the water, they receive the impressions of the light in a more direct manner than the *Dyticidæ*, and are accordingly ornamented with tints of a brassy or bronzed metallic hue, which glitter in the sun in the highest degree. The velocity with which they execute their evolutions upon the surface of the water is really surprising, and has obtained for them the name of tourniquets by the French, and whirlwigs and water-flies by the English. Sometimes, indeed, they remain stationary for a time, so that it seems easy to secure them, but on the least motion they are instantly alert, escaping

with surprising agility and diving to the bottom of the water. The situation of their eyes adds greatly to their defence, enabling them to see objects both above and below them. One of our most popular writers on natural history thus describes their proceedings:—"Water, quiet still water, affords a place of action to a very amusing little fellow (*Gyrinus natator*), which, about the month of April, if the weather be tolerably mild, we see gamboling upon the surface of the sheltered pool; and every school-boy who has angled for minnows in the brook, is well acquainted with this merry swimmer in his shining black jacket. Retiring in the autumn, and reposing all the winter in the mud at the bottom of the pond, it awakens in the spring, rises to the surface, and commences its summer sports. They associate in small parties of ten or a dozen, near the bank, where some little projection forms a bay, or renders the water perfectly tranquil; and here they will circle round each other without contention, each in his sphere, and with no apparent object, from morning until night, with great sprightliness and animation; and so lightly do they move on the fluid, as to form only some faint and transient circles on its surface. Very fond of society, we seldom see them alone, or, if parted by accident, they soon rejoin their busy companions. One pool commonly affords space for the amusement of several parties, yet they do not unite or contend, but perform their cheerful circlings in separate family associations. If we interfere with their merriment they seem greatly alarmed, disperse or dive to the bottom, where their fears shortly subside, as we soon again see our little merry friends gamboling as before."—*Journal of a Naturalist*, vol. i. p. 307. When they dive to the bottom of the water in the manner above described, they carry with them a little bubble of air affixed to the extremity of the body. Also they are sometimes to be found flying, their well-formed wings permitting such an operation, whilst the high polish of the body protects them from the action of the water.

With the exception of a few exotic species, the insects of this family are of a small size, seldom exceeding a quarter of an inch in length, and the largest ones do not reach one inch. Some of the species are found on the margins of the ocean. They emit, when touched, a disagreeable scent, arising from a milky fluid which exudes from the different parts of the body, and which is not readily dispelled.

The structure of the fore legs indicates their mode of life, serving as arms to convey the food which they find floating upon the surface of the water, and which consists of small dead insects, &c., to the mouth.

The number of species of this family does not exceed fifty or sixty, and of these not more than eight or nine are found in this country; of these the *Gyrinus natator* is the most common species. It is of a brilliant bronzy-black colour, with the sides of the body and antennæ metallic; the margins of the elytra and legs are reddish. The elytra are ornamented with lines of impressed spots. It is about a quarter of an inch in length.

**HABENARIA** (R. Brown). A genus of tuberous rooted herbs, indigenous to the northern parts of the world, some of which were formerly called orchis; they all belong to the natural order *Orchideæ*. They are cultivated in shady borders or in frames.

**HABRANTHUS** (Herbert). A genus of hardy

and greenhouse bulbs, some of them remarkable for the fine scent of the flower. They belong to *Amaryllideæ*. They are treated like other bulbs.

**HÆMANTHUS** (Linnæus). A highly ornamental genus of African bulbs, called blood-flower, from the deep colour of their blossoms. They belong to the sixth class of Linnæus, and to the natural order *Amaryllideæ*. Generic character: spatha of four or six valves, involving many flowers, and persisting; flowers in a dense bunch; corolla tubular at the base; limb six-cleft, regular and erect; stamens imposed on the tube of the corolla protruding; filaments awl-shaped; anthers incumbent; style simple; berry three-celled: these bulbs thrive best in sandy loam and moor-earth, requiring no water but when in a growing state, and are increased by offsets.

**HÆMATOPOTA** (Meigen). A genus of dipterous insects, belonging to the family *Tabanidæ*, and distinguished from the gad-flies (*Tabanus proper*) by wanting the ocelli, and by the antennæ, of which the terminal portion consists but of four joints, sometimes cylindric and subulated, the first being thick, and nearly oval, in the males. These insects, which abound in the neighbourhood of woods, are exceedingly tormenting to persons walking in such situations, settling upon the exposed parts of the body with a touch so slight that their presence is not perceived until they have contrived to insert their powerful proboscis into the flesh, causing a very acute pain. They are of smaller size than the *Tabani*, and their wings are elegantly ornamented with dark spots and rings upon a pale ground. There are several British species, the type of the genus being the *Tabanus pluvialis* of Linnæus. The name of the genus is derived from two Greek words, signifying sucker of blood.

**HÆMATOXYLON** (Linnæus). The *H. Campechianum* is the logwood of commerce, and belongs to the natural order *Leguminosæ*. Logwood is astringent, and both in decoction and extract has a sweetish taste, which makes it preferable to many other vegetable astringents as a medicine. The chief use of logwood is, however, as a dye-stuff; and for this purpose large quantities are imported into this country every year, from the British West Indies, Mexico, and the United States.

**HÆMODORACEÆ**. The name of a natural order containing ten genera, and above twenty-four species, chiefly cultivated in greenhouses. The name of this order, says Dr. Lindley, is derived from its blood colour, indicating its most striking peculiarity: the roots of several species of *Hæmodorum*, *Wachen-dorfia*, and *Heritiera*, yielding a brilliant crimson dye. The species have equidistant leaves, and six stamens, with anthers turned towards the ovary; in which last character they differ from the closely allied order of *Irideæ*. They are found, with few exceptions, at the Cape of Good Hope and New Holland.

**HAIR GRASS**. Is the *Aira flexuosa* of Linnæus, one of the British grasses.

**HAKEA** (R. Brown). A pretty extensive genus of Australian plants, belonging to the fourth class of sexual botany, and to the natural order *Proteaceæ*. The flowers are sweet-scented, and are desirable greenhouse plants, thriving in sandy loam and moor-earth, and propagated by cuttings.

**HALESIA** (Linnæus). A genus of North American shrubs or small trees, vulgarly called from the shape, colour, and position of the flowers, snowdrop

tree. They belong to *Dodecandria*, and the natural order *Styracineæ*. They are interesting shrubby plants, and are increased by layers or by cuttings of the root.

**HALICTUS** (Latreille). A genus of hymenopterous insects, belonging to the section *Aculeata*, sub-section *Mellifera*, or bees, and family *Andrenidæ*, or short-tongued bees. The characters of this genus will be found under the article *ANDRENIDÆ*; but as no account is there given of the economy of the species of the genus, we will take this opportunity of supplying the deficiency, chiefly from a valuable memoir, published in 1817, upon two of the species, by the Baron Walckenaer, a celebrated French naturalist. There is an extensive colony of one of the species established at the foot of the wall of the barracks in the turnpike-road near the entrance to Kensington palace, where we have often noticed the insects. Nevertheless the species are solitary in their habits, the individuals having no tie upon each other, and the congregation resulting merely from a convenient locality. It is a curious circumstance, that it is only during the night that the bees construct their nests, which consist of a perpendicular passage, extending to a considerable depth, and then branching off into several other shorter passages, at the bottom of each of which a mass of pollen paste is deposited with an egg, the ball of the former being about the size of a pea, and serving for the support of the larva when hatched. During the day either the male or female bee remains at the mouth of the burrow, in order to prevent the entrance of enemies, such as cuckoo-flies (*Tachinæ*), and ichneumons, or ruby-tailed flies (*Chrysididæ*). On the return of its partner, which takes two or three circular flights round the mouth of the burrow, the sentinel immediately withdraws into the nest to make way: moreover it is worthy of notice that, instead of alighting upon any adjacent object, as is generally the case with burrowing insects, the halicti fly at once into the nests; a circumstance attributed by Walckenaer to the desire to elude their enemies, of which there is a fearful catalogue, the most ferocious being the *Cerceris ornata*, of whose habits we have given an account under that genus. The preceding observations relate to the *Halictus terebrator* of Walckenaer, or the *Melitta fulvo-cincta* of Kirby, one of the smallest species of the genus; but in the other species observed by Walckenaer, *Halictus eca-phorus*, or the *H. 6-cinctus* of Latreille, which is one of the largest of the species, the habits are different in some respects,—large, strong, and fearing but little for the enemies which prey upon their smaller brethren, this species works by day, and during the greatest heat. The entrance to the burrows is large enough to admit two individuals at once, whereas in the other species it is only of the size of the head of the insect. The direction of the burrow is also different, and, instead of diverging into several channels, it terminates in a large round cell, two inches and a half in diameter and three inches high, filled with earthen cocoons, attached loosely together, leaving various channels between them. When examined, it is found to consist of about a score of earthen cocoons, each having the mouth closed, so that the enclosed inhabitant has no communication with the external air. The inner walls of the cocoons are finely polished.

**HALIMODENDRON** (Fischer). This genus of plants was formerly called *Robinia* by Linneus and

Heritier, and *Caragana* by Lambert: but finally described and renamed by Fischer. It belongs to *Leguminosæ*, and forms a pretty shrub in flower borders: may be increased by seed or by grafting on the *Caragana arborescens*. The plants are natives of Siberia, and are there called salt or sea trees.

**HALIOTIS** (Linneus, and modern authors). This well-known but elegant mollusc constitutes a well-defined genus, numerous in species, and remarkable for their *ear-like* form, whence the derivation of their name, sea-ear. As this shell is to be met with in every collection, a minute description of it, in scientific language, would here be useless; we will, nevertheless, give its general characters. The substance of the shell is internally brilliantly nacreous; it is extremely depressed, more or less of an oval shape, with a very small spiral termination, and very flat. The aperture is the full size of the shell; its edges continuous, the right one thin and trenchant, the left flattened, enlarged and sharp, parallel to the left side; a series of holes exist, which serve for the passage of the two-pointed lobes of the animal's mantle. There is only one great muscular impression. The animal is entirely covered by its shell. As the increase of the animal's size requires an extension of its protecting covering, a new hole is commenced, appearing at first only a notch on the margin, afterwards completed as the growth of the shell continues, and others are formed in succession, while the perforation nearest the spire is carefully closed in the same succession, leaving, however, in almost every instance, six holes at the same time open. When the animal is at rest it adheres, like the patella, to the rock or substance on which it is found, and can only be detached by a sudden effort, as they have resisted the application of a lever, till every portion of their shell was so far broken as no longer to furnish a point of resistance. An ingenious naturalist has calculated that it would require at least a ton weight to force these shells from their resting place, could the substance of them withstand the application of the necessary mechanism, such is the perfect vacuum formed by the animal. There are probably few of our readers who, in the early part of life's dream, have not witnessed this philosophical fact by the simple application of a piece of wet leather to any heavy substance; as the subject, however, is most ably explained in the First Division of this work, we need not here go into it, but proceed with a description of the animal constructing the haliotis. Its body is of a very depressed oval shape, slightly spiral backward; it is provided with a large foot, doubly fringed round its circumference; the head flattened, tentacula conical at the base, and a little flattened; the eyes are placed at the summit of prismatic peduncles, situated on the external edge of the tentacula; the mantle is very thin, deeply divided on the left side; the two-pointed lobes form, by their junction, a canal to conduct water into the bronchial cavity, situated on the left side, and inclosing two very long, unequal, bronchial combs. These molluscs adhere to rocks nearly on a level with the sea, and, during the fine summer nights, wander to feed on the herbaceous plants that grow near the shore. Their flesh is considered good eating, and in Guernsey they are sold in the market in common with other shell-fish. Lamarck sub-divided this genus, separating from it those species which were imperforate (or without holes); his *Stomatia* is an

instance ; this Linnæus named, with great propriety, *Haliotis imperforata*. Leach also formed a genus, which he named *Padollus* ; but these have all been united by the modern French naturalists, who make them merely sub-divisions of the *Haliotis*. These molluscs inhabit the seas of all parts of the world, and vary greatly in size, the writer of this article having possessed them from the 10th of an inch to 18 inches in length. A number of the latter magnitude, some years since, were brought to this country, it was said from California ; but of late years no such large examples have been imported from any country whatever. It is believed that no fossil examples of *Haliotis* have ever been discovered. The genus is ranked in the second class, *Paracephalophora*, third order, *Scutibranchiata*, first family, *Oliæda*, in which the organs of respiration are constantly situated on the animal's left side. This genus might, doubtless, become more clearly defined by an elaborate classification of its species in their natural proximities ; but it would be impossible to point out any thing more characteristically marked than these molluscs are from every other known.

**HALIPLUS** (Latreille). A genus of coleopterous insects, belonging to the section *Pentamera*, and family *Dyticidæ*, and distinguished from the other genera of this family of water-beetles by having the base of the hind legs covered by a large shield-like plate composed of the dilated coxæ of these organs ; the palpi are also terminated by a minute conical joint, in which respect they resemble the minute species of *Bembidiidæ* (belonging to the adjoining family *Carabidæ*), which are also sub-aquatic in their habits, whence these insects have, by some systematists, been considered as forming the point of connection between the two groups. The species are very numerous, of very small size, and may be constantly observed swimming about with great agility in almost every running or standing water ; the type of this genus being the *Haliplus elevatus*, which is at once distinguished by the elevated lines upon the elytra.

**HALLERIA** (Linnæus). Ornamental greenhouse shrubs, from the Cape of Good Hope. The flowers are didynamous, and belong to the natural order *Scrophularinææ*. The plants grow freely in an equal mixture of loam and moor-earth, and are propagated by ripened cuttings in sand.

**HALLIA** (Thunberg). A papilionaceous genus of plants cultivated in the greenhouse, and succeeds with the ordinary treatment thereof.

**HALORAGEÆ**. A natural order, containing, according to the Hortus Britannicus, seven genera, and about twelve species, which, according to the same authority, are mostly obscure weeds, distinguished from *Onagrarice* by their naked and solitary ovula. They are natives of moist places or ponds, in various parts of Europe and North America. Some of the species of *Haloragis* are tropical. They are not known to possess any medicinal properties.

**HALORAGIS** (Forster). A genus of small New Zealand plants, belonging to *Octandria Tetragynia*, and to the natural order to which they give a title. They require greenhouse management.

**HALTICA** (Geoffroy). A very extensive genus of minute coleopterous insects, belonging to the section *Tetramera*, and family *Galerucidæ*, distinguished by the large size of the hind thighs, which enable the insects to leap about with great agility. They are

for the most part ornamented and varied with brilliant colours and shining bodies, and commit great havoc upon the leaves of vegetables, both in the larva and perfect states. The greatest number of species are, however, found in South America, but these are for the most part of a much larger size than those found in our own country. From the extent of the genus it has become necessary to subdivide it extensively. Illiger did this in the *Magazin der Entomologie*, proposing nine sections, which more recent authors, as Latreille and Stephens, have regarded as so many distinct genera.

It is to this genus that the small insect belongs, which is generally known under the name of the *Turnip-fly*\*, but which, as there are several hymenopterous *fliæ* which likewise feed upon the turnip, it would be more proper to distinguish as the *turnip-flea*, naming it thus in allusion to its leaping agility. The ravages of this minute insect upon this valuable plant are unfortunately too well known to agriculturists to need much description. The insect is indeed one of the most formidable that can attack a crop. What possibly can be more harassing to the farmer than to see a fine thriving field of turnips just appearing in leaf, destroyed in the course of a day or two by enemies which are so minute as almost to escape detection, and so obscure in their habits, as up to the latest moment to have escaped in this respect the observation even of practised observers of insects ? Whilst doubting too whether his crop may possibly recover, the unfortunate agriculturist may lose his season for second sowing, or he may again encounter a similar risk by resowing his land. Plans have been, and still continue to be tried, with partial success, and in consequence thereof they have been published to the world as unerring remedies ; but so long as the real economy of the creature remains unknown, it is impossible to arrive at any other conclusion than that such success has been obtained by chance, particular circumstances of locality or season having produced effects which have been attributed to some much more general cause, but which have been found totally inapplicable when those particular circumstances have ceased to exist.

Under these circumstances, the Doncaster Agricultural Association, in 1830, proposed the turnip-fly as an advantageous subject of inquiry, and a series of inquiries were issued, directed to numerous agriculturists and entomologists, seeking for information from both relative to the subject. A great variety of information, of a very valuable nature, was thus obtained, and from the published Report of this association, the following particulars are concisely derived :—It appears that although the months of May and June are stated as the period of the first attack, the insects appear much earlier, and are ready to attack the turnips first sown. It is evident, therefore, that the beetles have previously undergone their preparatory changes elsewhere than upon the turnip plant ; and this is an important fact, a point gained in the

\* This insect is systematically described under the name of *Haltica nemorum*, Linnæus (by whom it was placed in the genus *Chrysomela*) ; it is of an oblong oval form, slightly depressed above, of a black colour, the elytra having a greenish tinge, and each being ornamented with a broad longitudinal stripe of a pale brimstone colour. It is about one-twelfth of an inch long. There are also several other species very nearly allied to it, having similar habits, and being not less injurious, some of which possess the pale stripe on the elytra, while in others it is wanting. They may all be distinguished by the thickened hind-legs.

economy of the insect, which has been too much overlooked. Again, it is stated that no period of sowing is too late, provided the weather be warm, for the attacks of the insects; hence the season for the ravages of the insect may be said to coincide with the season of vegetation itself. As to the stage of growth of the plant, it appears clear that the mischief is caused during the growth of the cotyledon leaves; if the plant is sufficiently strong to put on its second series of rough leaves, the insect, although it may continue its attacks, has not sufficient power to do much damage. It likewise appears that it is in hot, and especially in hot damp weather, that the insect is most prejudicial. As to soils, the correspondents agree that no soils whatever on which turnips can be cultivated at all are free from the insect; and in like manner no manure at present known will prevent its approach, although that manure which most effectually promotes the rapid growth of the plant, and the throwing out of the rough leaves, will at the same time be the most effectual defence against the insect.

Turnip Fly.

As to the mode of sowing to be adopted, the answers are decidedly in favour of the drill system over broad east, by bringing the plant more immediately into contact with the manure, and by forcing forward the plants from the thickness in which they stand in the rows; and lastly, that regular management, and a high state of cultivation, are highly important in ensuring regular success, lands in the best condition escaping best. The turnip-fly, moreover, feeding also upon many hedge weeds, and sheltering itself in rough grounds, nothing would tend more effectually to prevent its accumulation than by early clearing off both its shelter and food as far as possible. Thus much is given as relates to the attacks of the insect, but of its natural history no decisive information was obtained by the Doncaster Agricultural Association. It is said that "this part of our inquiry is by far the most important; and, important as it is, cannot in the present state of information be fully answered." Can it be doubted that this is not the most important part of the inquiry? How is it possible that successful remedies can be applied whilst some persons assert that the insect is produced from eggs placed by the parent beetle upon the turnip seed, and others that it is thrown into the earth with the manure? The report proceeds: "Under these circumstances all speculations, as to the abode and habits of the infant turnip-fly, must be vague and unsatisfactory. We need not say how very important it is that these facts should be ascertained, and that we should know where the enemy is generated and nurtured, as well as the length of time occupied in each transformation. An extensive series of experiments undertaken on this subject might be of the utmost advantage, and eventually prove a national benefit. It is possible that in its infant stages the insect may be destroyed more effectually than in any other; and at all events an accurate

knowledge of these facts would confine the efforts and experiments of the farmer within certain limits, from which they must now, in our ignorance, be continually diverging, and much time and effort now wasted on impossible experiments would be saved." To this, therefore, the natural history view of the question, it is our duty to direct, in an especial manner, the attention of our readers.

It only remains for us to notice the most advisable remedies suggested for preventing or alleviating the attacks of the insect. Of such as relate to the steeping of the seed, or the mode of the sowing of the seed, we are silent, as it is quite clear, from what is known of the habits of the insect, that they are untenable, save as relates to the more quick forcing of the growth of the plant. An expedient which seems partially successful consists in sowing with the turnips the seeds of some other plant, which may be more grateful to the taste of the insect, as when Swedes and white turnips were sown together the former escaped. Fumigation and the burning of stubble on the windward side of the field has been found to answer, as has also the scattering of vegetable ashes or soot upon the plants; repeated watering of the plants also, where practicable, has been found successful; but the most universally practised method, and apparently much more certain of success, is to spread quick lime over the young plant, as soon as out of the ground, spreading it on and around the plant, and repeating it as often as wind and rain shall have cleared it off, until the plant be out of danger. Lime is so common that it can be had in all situations, and it is so cheap that the cost need not embarrass the farmer. The labour is so comparatively small that it is capable of being generally adopted, and if the fly should not appear the lime can be used for other purposes. It seems also to be advisable that the lime should be laid on in a hot state rather than after it is slaked. It would be easy and very desirable that it should be spread by some machine rather than by the hand. Some of the correspondents, indeed, urged an objection against this plan, that the quick lime injures the plant and prevents its growth, but from the more decided observations of others, the Association recommend "That as soon as the plant appears above ground it be dusted with quick lime, and this repeated as often as rain or wind beats it off, and the fly re-appears."

We had written thus far when we ascertained that the Entomological Society of London, by whom the turnip-fly had been selected as the subject for one of the prize essays established by the society, has just received an account of the insect in question, from the pen of Mr. Le Keux, in which an account of the preparatory stages of the insect is given. The particulars of this communication, read at the last January meeting of the society, have not indeed transpired, but we trust that the society will lose no time in laying before the public a document which may prove of such vast importance to the agriculturist.

**HAMAMELIDÆ.** A small natural order, containing only two genera, and about half a dozen species. The *Hamamelis* is the Witch Hazel of North America; and the other genus is the *Fothergilla* from the same country, both hardy shrubs and common in our collections. Both are increased by layers. Little is known of the general properties of these plants. The bark of the *H. Virginica*, which is bitter, has been used medicinally; and poultices made of it are said to relieve inflammatory tumours.

**HAMELLIA** (Linnæus). A genus of West Indian evergreen shrubs, belonging to the class *Pentandria*, and to the natural order *Rubiaceæ*. This is an easily managed free-flowering genus, thriving in loam and moor-earth, and striking root readily from cuttings.

**HAMITES** (Sowerby). A shell only known in its fossil state; it may be considered a species of *Ammonites*; it is frequently found in the old formations, though generally as an imperfect mould. Both Sowerby and DeFrance have described many species.

**HARDWICKIA** (Roxburgh). A genus of lofty trees, natives of the East Indies, and belonging to *Leguminosæ*. Generic character: calyx of five sepals; corolla none; stamens alternately long and short; anthers oval with a point; style ascending; stigma headed; pod membranaceous, lance-shaped, and one-seeded. The plants affect rich loam and moor-earth mixed, and may be rooted from cuttings.

**HARE** (*Lepus*). A genus of rodent or gnawing mammalia. One of the most remarkable, the most natural, and the most numerous, and to man the most interesting of the whole class. The animals of this genus are distributed, in one species or other, over most countries on the face of the earth; and though New Holland forms a total, and South America a partial, exception, hares properly so called, or the allied subgenera, which agree well with them in their main characters, are found almost everywhere: in the warm countries, on the margins of the deserts, on the sandy downs by the sea shores, in the corn fields, in the upland wilds, and on the tops of the mountains, to the very verge of the never-thawing snow. In longitude they extend round the whole circle of the earth, and their range in latitude is at least from the Cape of Good Hope to the borders of the Polar ice.

Nor are the principal species held in less estimation as human food. In the British islands, the hare is now almost the only four-footed animal, the chase of which in wild nature is anything else than mere sport; and then of those species which live more in society than the common hare, and approach more nearly to a state of domestication, the numbers in favourable situations are so great, that large profits are made by the sale of them. This is especially the case with the rabbit. The warrens where those animals are encouraged, in general occupy situations which are not very fit for any other useful purpose; and the animals breed so fast that a supply or produce, equal to several times the number of the necessary stock, may be brought to market every year; and their successive breeding is so rapid under favourable circumstances, that rabbits are scarcely ever out of season, if the stock is properly managed; for as soon as one generation ceases to be fit for the market another is ready to come in. Some of the sandy islands in the bays and estuaries of this country are so perfectly crowded with rabbits that the inhabitants scarcely eat anything else; and they might make the same reply which the Shetland boy made to the third inquiry of the traveller respecting the colefish or "piltocks," which are the principal food of the labouring class in many of those northern islands. "Piltocks" was the answer to what was got for breakfast and for dinner; and when the question was put as to supper, the reply was, "What *could* I get but piltocks?" Just so might the people of some of the sandy islands

reply with regard to rabbits, more especially the people of some of the islets in the Bristol Channel.

The characters of this interesting and extensive genus are, four incisive teeth in the upper jaw, and only two in the under; six grinders in each side of the upper jaw, and only five in each side of the under. Those grinders are without proper roots, but have bony tubercles upon the surface, broader across the jaw than in the direction of it. The anterior one is a little smaller than those which immediately follow it; and the posterior one is still smaller. All these grinders, except the last one, have their crowns divided into two parts by a transverse furrow, but the last one presents only a few irregularities in the sides. The grinders in the lower jaw have their crowns divided in the same manner as those in the upper; but they differ from these in having the length along the jaws nearly equal to the breadth across it. By this conformation of the grinders the animals are enabled to masticate bark, twigs, and other very hard substances; because the grinders apply against each other in such a manner that every one bears upon two, which offers a much stronger resistance than if the action were that of tooth against tooth. The incisive teeth are long and large, and flattened on their external surfaces. Of the four in the upper jaw the two middle or principal ones are long, strong, and divided throughout their length by a deep furrow, the portions on each side of which are rounded externally; so that the cutting extremity of the tooth has something the form of a double gouge. Of those prominences the lateral or external one on each tooth is the broadest and strongest; and thus this apparatus combines the very maximum of mechanical skill and strength in proportion to the quantity of materials. The two shorter incisive teeth, which are external of these, serve chiefly to support them, which they do much more effectually than if they were of the same length. They are rounded in their section, and stand rather broad upon the jaw, by which means they still farther support the two middle ones. The middle ones have an oblique basil on their posterior faces, which brings them up to a chisel-edge on their anterior ones; and while the body of the tooth is composed of bone which is tough and fibrous, though comparatively soft, the plate of enamel on the anterior or cutting edge is exceedingly hard. This is by no means an uncommon structure of tooth among rodent or gnawing animals; and no structure can be better adapted for their purposes. This tooth wears at the top by the hard substances which the animals divide, and are compelled to divide, especially in the winter months, when there is no longer any green food for them. But though it wears, it has no tendency to get blunted, as the supporting bone wears fully as fast as the supported cutting edge; and as such teeth continue growing at the roots, they remain fit for action during the life of the owner. The two teeth in the under jaw have cutting edges, and are supported by bone nearly in the same manner as those in the upper.

The bodies of these animals are as peculiar and characteristic as the forms of their teeth. The fore legs are slender, and in all the species much shorter than the hind legs. The fore legs have five toes armed with claws, which are strong and rather crooked. The third toe is the longest in the foot, and the fifth, or that which answers to the thumb, is short, placed on the metacarpal bones, and does not touch the ground in walking. The hind feet have only four

toes each. All the toes, and even the soles of the feet, are covered with hair similar to that on the rest of the body; and this character has been considered as a distinguishing one from the earliest periods of natural history, and on account of it the genus has sometimes been called *Dasyypoda*, or hairy foot. The tail, which is generally thickly beset with soft hair, is always short, and in some of the species is entirely wanting.

The ears form a distinguishing natural character in these animals; they are usually very long, and capable of much more motion than the ears of most other animals. In the natural state their common attitude is erect; but in some of the domesticated varieties (for the domesticated ones are very much broken into varieties) they are pendulous. In general the ears are naked, or very thinly covered with short hairs; and the membranes of which they are composed are so thin, that they are transparent or nearly so, at least a strong light shines through them. The upper lip is entirely slit or divided on the mesial line; and this is so marked a character, that the common name given to a divided lip is a hare lip. The external part of the mouth is partially covered with hair. The eyes are large, stand far out from the head, are placed laterally, and capable of commanding nearly the whole horizon; that is, seeing behind the animals as well as before without turning the head. The nostrils are straight; and in the upper part there is a transverse membrane which can occasionally be brought down, so as nearly to close the orifice.

The females have a variable number of mammae, in the different species or rather subgenera. The greatest number is ten, and the least number six; and whatever the number is, there are always four pectoral, or on the breast, and the remainder abdominal or on the belly. In the hares and rabbits, which may be considered as the typical species, or the true hares, the number is always ten; and though it does not hold universally that the number of young increases with the number of mammae, yet it is natural to suppose that the general tendency is that way.

We have already mentioned that these animals are exceedingly prolific; and the females of them are among the few in which the singular process of *superfoetation* takes place; that is, a new conception happens after the young one, already in the matrix, is considerably advanced. But though this does take place, all the animals of this genus are true placental mammalia, and have not in the system of reproduction, any approximation to the structure of the marsupial animals.

There is, however, one circumstance here which is not a little wonderful, and which shows that we are to seek the characters of animals in the whole animal and not in any individual part; that, in short, independently of the matter of which the body is composed, and the organs and the form into which that matter is moulded, there is something, even anterior to this matter and this form, which collects the one and fashions the other. The animals of this genus make a nearer approach, in their general form, their gait when walking, and their mode of life, to the rodent marsupial animals, that is to the kangaroos, especially the smaller ones, than is made by any other race, indeed than is made by any two races in the whole class of mammalia, the one of which is strictly placental, and the other marsupial. And in the kangaroos this tendency to *superfoetation* is far stronger

and more common than in the genus *Lepus*. So strong is it indeed that, when they are in free nature, there is perhaps no instance of a female kangaroo which has not two or more successions of young ones bringing forward at the same time. We shall have occasion to make some further remarks on this very singular portion of the economy of nature, when we come to the article KANGAROO, in the course of the alphabet; and we trust that before then we shall be in possession of two or three little points which are yet wanting, before the physiological history of those most extraordinary animals is complete. The present analogy is, however, of too striking a nature for being passed over without notice, and therefore we have introduced it to prepare such of our readers as may be fond of inquiring into the wonders of Nature's modes of working, for what we may have occasion to advance in the article above alluded to.

The hares admit of convenient division into two sub-genera; hares properly so called, *Lepus*; and rat-hares, *Lagomys*.

**HARES PROPERLY SO CALLED (*Lepus*).** These, besides the common characters of the genus, as already described, the hares properly so called, have certain characters of their own. One of these is colour, which, in a state of nature, is always greyish-brown, except in some of the Alpine species, and their colours appear to be climatal and seasonal. Another coloured mark, which distinguishes them in a state of nature, is a spot over or around the eye. In many this spot is white, in all it is lighter coloured than the surrounding parts, and it is never wanting. The tail is also invariably white on the under side, and generally blackish on the upper, except in the American rabbit, in which it is reddish. With the exception of the sides of the neck, the upper part, including the outsides of all the legs, is generally of the same colour as the back; the under part is white in almost all the species, and the tips of the ears are black; the body, the upper part especially, is covered with two sorts of hair, the one long and silky, and rather strong in the staple, the other shorter, more woolly, and much finer, and therefore extensively used in the manufacture of hats, in which it is frequently employed as a substitute for the fine woolly hair of the beaver, to which, however, it is greatly inferior, both in strength, and in retaining the colour given to it by dyeing. The hair of the rabbits is still greatly inferior to that of the typical hares in this respect, but it is also used, though hats made of rabbits' felt are of exceedingly little value.

The other remarkable character of the true hares which we shall mention is their extreme productiveness. They are capable of breeding during the first year; the females go only thirty days with young; the broods are often numerous; and the young are born completely covered with fur, with their eyes open, and are very soon in a condition for finding their own food. Many of the species dig burrows in the ground to a greater or less depth; and those who do not, are in the habit of selecting for themselves particular seats or "forms," upon which they rest, not only during a portion of the night, but during the greater part of the day. The morning and the evening are their principal feeding-times; and while the sun is bright they are but rarely seen, though, in gloomy days, and especially after a shower, they do come abroad, though the young do this more frequently than the old ones. On their forms they

sit very close; and as these are generally chosen upon dry knolls, or other places where there is withered vegetation, one may pass so near them as almost to tread on them without their rising. This is not only the case when there is no danger abroad, for there have been instances in which those who were following the greyhounds, in coursing, have picked up a live hare within a yard or two of where the dogs had passed not a minute before. The species are very numerous, but we can find room for only a few of the more remarkable.

**THE COMMON HARE** (*L. timidus*). It is scarcely necessary to describe the appearance of an animal so common and so well known; but the following may be regarded as a summary of the leading characters:—The inside of the mouth is hairy; the tongue and nose are very thick; the upper lip is cleft to the nostrils, which seem to unite, and to form a single opening; the eyes, which are very prominent, are furnished with a nictitating membrane; the feet are covered beneath, as well as above, with fur; the heart is proportionably large, and the cæcum about six times as large as the stomach. Under the Mosaic dispensation, when various animals were described as clean or unclean, according to the Levitical ritual, the hare is described as “chewing the cud,” that is, as being a ruminant animal. That the hare is not a true ruminant, and furnished with the compound stomachs of that class of animals, is certain; but still it says not a little for the truth of the Bible’s natural history, that the hare is still a partial ruminant, and that, while she sits on her form, she can occasionally bring up a portion of her food, and give it a second mastication. It might not be worth while to notice this fact, were it not that, on account of it, some persons have taken an exception to this part of the Bible. Hares, even of this species, are common in most parts of the world, though they vary considerably in size in different places. Generally speaking, they are smaller in hot countries than in cold; and we might expect this, because the general investiture of the whole body, feet and all, with fur, naturally points out the hare as more an animal of cold, or, at least, temperate countries, than of warm ones. It has been observed, however, that, in places not very different from each other, either in climate or in situation, there are great differences of appearance in the common hare. We shall afterwards have occasion to advert to the Irish hare, which recent observation has shown to differ greatly from the hare of Britain, near as the islands are to each other; but we may mention, that a very small breed exists in the island of Islay, on the west coast of Argyleshire, and a very large one on the Isle of Man, where individuals have been taken that weighed twelve pounds. In England examples occur of hares weighing from ten to eleven pounds; but from some of the rich districts in the east of England hares of much greater weight are frequently sent to the London markets, some weighing as much as fourteen and fifteen pounds. The kind provisions of nature, for the preservation of this race of animals, are equally numerous, and calculated to command our admiration, and afford a striking proof, among thousands which might be produced, of that system of compensations, that balancing of perfections and defects, that equalising of the quantity of life and destruction, on which the continued existence of the respective tribes of animals depends. On the one hand, if the hare is exposed to the

attacks of beasts of prey, on the other it is abundantly fruitful; and, if often pursued, it is also furnished with various sources of evasion and escape. Its ears are so contrived, as to convey even remote sound from behind; and the eyes, as already mentioned, of the class generally, are so situated as to enable it, when it rests on its seat, to observe without difficulty, and even without much motion of the head, a whole circle; and, though it sees but imperfectly in a straight line forwards, it can direct its vision to whatever threatens it in the way of pursuit, and the eyes are never entirely closed while the animal sleeps. From the powerful muscularity of its limbs, it can sustain the fleetness of its course for a considerable time, while the greater length of the hinder legs gives it such a decided advantage in ascending, that, when started, it always makes to the rising ground.

Its habitual timidity, and perpetual apprehension of danger, preserve it lean and in a condition the best adapted to profit by that speed which forms its security. In dry or frosty weather the thick hairy covering to its feet also gives it an advantage over the dog which pursues it. Its close approach in colour to the soil, often conceals it from the sight of man and predacious animals; and, in northern countries, its fur frequently becomes white in winter, so as scarcely to be distinguished from the surrounding snow. As if conscious of its resemblance to the earth on which it treads, it has frequently been known, when closely pursued by the hounds, to squat immediately behind a clod, and suffer the dogs to run over it, which they no sooner do than it instantly starts off in a contrary direction, and thus deceives them. As it possesses the sense of smell in a pre-eminent degree, it is often aware of the presence of an enemy before it can ascertain its danger by sight. The doublings of its course are familiar to every sportsman; and though its sagacity seems to be in some respects at fault, especially in exhausting its strength in the early part of the chase, and in returning to its resting-place by the same paths, it has been frequently observed to have recourse to stratagems, which in the human being would bespeak not only presence of mind, but a prompt and practical application of the reasoning principle. If undisturbed, the multiplication of hares would prove greater than that of most quadrupeds; for at all seasons they are capable of breeding, and from the first year of their existence, while the term of gestation does not exceed thirty-one days. The hunters allege that when the produce consists of more than one, each leveret is marked with a star-like appearance on the forehead, which usually disappears with the first shedding of the coat, but sometimes continues to a more advanced period. Sir Thomas Brown, in his “Treatise on Vulgar Errors,” asserts, from his own observation, that female hares frequently have in their ovaries, at the same time, young ones of different ages, and that after those which are mature are brought forth, those will remain, which are very far from the term of their exclusion. This phenomenon of superfætation in the hare is confirmed by Buffon, who has explained it upon anatomical principles. However, the observation is at least as old as Herodotus. The breeding-place is usually under a tuft of grass, or high brake, a bush of heath, brush-wood, or standing corn. The young are suckled by the dam for about two weeks, after which they separate, and procure their own food, making their forms at sixty or seventy

paces from each other ; so that when we meet with one young hare we may be pretty certain of finding more within a very short distance. The hare arrives at maturity in one year, and is supposed to live eight or nine ; but it is presumed that a small number, comparatively, are allowed to die of old age, for dogs of all kinds pursue them by instinct ; the cat and the weasel tribes are constantly lying in ambush, and practising their wary arts to seize them ; while birds of prey are still more formidable enemies, as against them no swiftness can avail, nor retreat afford security ; and lastly, man, more powerful than all, sacrifices great numbers, for his pastime or his subsistence.

The hare is rarely found in very hilly or mountainous situations ; neither is it often found in places much exposed to the wind, especially when it blows from the north or south ; its favourite residence being in rich and somewhat dry and flat grounds. The hare-finders and shepherds remark, that the hares on the downs have a variety of seats, which they shift from time to time, as the weather directs, generally ascending to the more elevated grounds when rain prevails. Their food consists of various vegetables, but they seem to prefer those of a milky succulent quality, and to be very partial to pinks, carnations, parsley, birch, and laburnum. They will prey on the bark of almost every tree during winter, and they are often very injurious to young plantations. Their cry, which has been compared to that of an infant, is seldom heard, except in cases of distress or surprise. They are taken in some countries by a call imitative of that between the male and female.

The hare is naturally of a gentle disposition, although not very susceptible of strong attachment, and when taken young may be tamed with very little difficulty. Shy and timid as it undoubtedly is in its native haunts, yet, when domesticated, it often assumes a forward and even a petulant demeanour. In respect of disposition, however, a very marked diversity probably obtains among different individuals, as has been finely exemplified by Cowper the poet, in his account of three which he watched himself.

As an article of food the flesh of the hare has been in high esteem from very remote antiquity ; and notwithstanding the additions which modern luxury has made to the furnishings of the table, it still maintains its character. In the opinion of Martial the epigrammatic poet, the flesh of the hare was superior to that of every other four-footed animal ; and Horace represents the hare's "wing" as being among the most highly prized of Roman luxuries. In those countries of middle and southern Europe which are but thinly peopled and partially cultivated, as compared with the British islands, the number of hares which are taken in the course of the year is immense ; and the skins of them form an extensive branch of commerce, being exported for the hat manufacturer, and also used locally as very warm articles of clothing. It is understood that the small kingdom of Bohemia alone furnishes nearly half a million of skins in the course of the year, and that Austria Proper furnishes nearly double that number ; while the supply from southern Russia and western Siberia is understood to be still greater.

Though the hare is considered as one of the most harmless and timid of all animals, excepting in so far as it commits depredations upon the vegetable kingdom, it has not escaped being made an object of superstitious dread ; neither is it quite exempted from those

foolish, and perhaps instinctive, prejudices which certain individuals of the human race have against certain animals which cannot in the nature of things do them any harm. It is reported of a celebrated French commander, who was an exceedingly brave man, that he always fainted at the sight of a hare. In our own country, when the belief in witchcraft was general, the hare was regarded as one of the most formidable animals,—the one, in short, into which old women most frequently transformed themselves, by the instrumentality of the devil, in order to wreak their vengeance on the rest of mankind. Nor has this prejudice been entirely exploded, for there are still many of the fishing villages where a hare's foot cannot be mentioned without exciting the greatest terror,—where a hare thrown into a boat would prevent that boat from going to sea ; and where, if such a catastrophe were to happen as a hare to run along the beach in front of all the fishermen's huts, it would shut them up as effectually during the day as if each were guarded by a regiment of soldiers.

THE ALPINE HARE (*L. variabilis*). This is the only species of hare which is found in the British islands besides the common hare mentioned in the former part of this article. The present one is far from common in our islands, though by no means rare in some other parts of the world. It is found, however ; but we believe only on the Scottish mountains, the wildest and most remote of these, and never lower down than two thousand or fifteen hundred feet above the level of the sea. It is not so long in the legs as the common hare, probably because the places which it inhabits contains fewer enemies which can pursue it on the ground. It inhabits higher up than the locality of every predatory quadruped ; and running would be but a vain defence against the rush of the mountain eagle, which is the chief if not the only animal which this hare has to dread in the fastnesses of its mountains. The difference of length in the legs is about an inch in the fore ones, and nearly two inches in the hind ; so that it is an animal of more uniform course, and less disposed to leaping, than the common hare. In the body its dimensions are nearly the same ; and from the specimens which we have examined in their native localities, we are disposed to consider it as being altogether thicker and weightier than the common hares of the lowlands in the same parts of the country. One of the most remarkable peculiarities of this animal, and one in which it agrees with the ermine among mammalia, and the ptarmigan among birds, is the seasonal change of its colour, excepting one part, which remains constant during the whole year, and is its permanent characteristic colour as a hare ; this is, the tips of the ears are black at all seasons. In summer the colour on the upper part is dusky, more or less inclining to fawn colour, and sometimes dappled, at least in the intermediate seasons. In winter it is altogether white, with the exception of the tips of the ears as aforesaid. The following account of the changes of its fur is from the second volume of the Edinburgh Philosophical Journal, and we believe it is correct :—"The varying hare becomes white in winter. This remarkable change takes place in the following manner : About the middle of September the grey feet begin to be white, and before the month ends all the four feet are white, and the ears and muzzle are of a brighter colour. The white colour gradually ascends the legs and thighs, and we observe under the grey hair whitish

spots, which continue to increase till the end of October; but still the back continues of a grey colour, while the eye-brows and ears are nearly white. From this period the change of colour advances very rapidly, and by the middle of November the whole fur, with the exception of the tips of the ears, which remain black, is of a shining white. The back becomes white within eight days. During the whole of this remarkable change in the fur no hair falls from the animal; hence it appears that the hair actually changes its colour, and that there is no renewal of it. The fur retains its white colour until the month of March, or even later, depending on the temperature of the atmosphere, and by the middle of May it has again a grey colour. But the spring change is different from the winter, as the hair is completely shed." This species, even during the most intense cold which occurs in those elevated and northern regions of which it is a native, keeps up the character of the race in the rapidity of its circulation and the high degree of its temperature. Even there it is as warm as one hundred and five degrees of the common thermometer, which is nearly ten degrees higher than in the human body. True to this activity of its system, the Alpine hare never shows the least disposition to hibernate, or pass into a state of torpidity, even in the severest winters; and for great part of the year at least (its haunts have comparatively few visitors in the winter) it evinces nearly the same fertility and disposition to breed as those of its congeners which inhabit the most fertile places. It is altogether a very interesting animal, on account of the peculiarity of its haunts and the determination, or rather the adaptation, with which it braves the utmost severity and duration of the winter storms. In the winter months, even when the storms are most severe and the snow lies longest upon the ground, those hares do not descend to the low grounds, but reside in burrows under the snow. Those burrows are usually made near the root of some tuft or upland bush, by means of which a sort of chimney is kept open for the breathing of the animal, and it feeds upon the substance of the tuft. As it preserves its high temperature during the rigour of the weather, it also of course keeps up its rapid circulation, and requires a corresponding quantity of breathing and of food. All those circumstances go together in every animal; for in those species which sink into a dormant state during the winter, the temperature sinks at least nearly to the freezing-point in some of the species, though we are not aware of any warm-blooded animal that recovers if its internal temperature has been for some time below freezing. Under the snow, and with their thick and white fur, these animals have no uncomfortable place of residence. Snow, till it melts, is a bad conductor of heat; and therefore the shelter of unmelted snow is really warmer than that of a hole in the earth. The white fur of the animal prevents the escape of heat from its body to the snow around it, and the warm air which it gives out in breathing speedily mounts up in the colder atmosphere, producing comparatively little effect on the breathing chimney. In a sunny day, when the air is still and clear over the snow, the retreats of these animals can be discovered by the little column of steam which ascends from the breathing-chimney, and which forms a sort of miniature picture of the smoke from the snow-house of an Esquimaux. There are some characters which we omitted to mention, in which the Alpine hare differs from the com-

mon one. Among others, the ears are shorter in proportion; and the silky, or long fur, is of rather finer staple. The fur altogether is, however, the fur of a hare, and not of a rabbit.

**THE IRISH HARE** (*L. Hibernicus*). This animal has not, we believe, got a name of its own in general circulation, neither was it suspected to differ from the common hare until of late years, when the two were examined in juxtaposition with each other. So far as we are aware, this species is confined to Ireland, at least no mention of it has been made by any of the continental naturalists. The colours are very nearly those of the common hare; but it is smaller in size, shorter on the legs, has the ears shorter, and the head shorter and more rounded. Its fur too is tender and of little value, being much more like the fur of a rabbit than that of the hares of Britain. Indeed, though it is called the hare in Ireland, it appears to have altogether a good deal more of the rabbit character.

**THE RABBIT** (*L. cuniculus*). The rabbit, in a state of nature, is considerably less than the hare; the ears are shorter than the head; the tail is not so long as the thigh; and the whole action and motion of the animal less vigorous and fleet than those of the hare. The general colour in a state of nature is yellowish grey, with reddish on the neck and brown on the tail, with the throat and belly whitish. The ears are grey, and without any black on the tips. The rabbit is a native of warmer climates than the hare; and it is altogether an animal of different habits. The hare inhabits only where there is cover, at least to some extent, while the rabbit is met with in the open and sandy wastes. The hares never burrow in the ground, but the rabbits always do; and they live in solitude, while the rabbits are generally gregarious. Rabbits have been known from the earliest periods of history, and the first or earliest accounts which we have of them represent them as inhabiting the warm and sandy places of southern climates, especially those near the shores of the sea. We are informed by Pliny that Spain and Greece were those countries of Europe in which rabbits were first found; and it is related both by him and Varro that an entire town in Spain was overturned by the incredible number of rabbits which lodged under its foundations; and Strabo tells us that the people of the Balearic islands, apprehensive that their country would be rendered desolate by the vast multiplication of these creatures, sent deputies to Rome, to implore military aid against this novel description of enemies. The Spaniards, in subsequent periods, thinned their numbers by means of ferrets, which they had imported from Africa. It is asserted by Spallanzani, that when the crops were wasted in Basiluzzo, one of the Lipari islands, by an extraordinary increase of rabbits, the inhabitants had recourse to large importations of cats, which in a very short period of time entirely destroyed them. It is supposed that the species was originally confined to Africa, and was afterwards diffused over the warmer and milder parts of Europe and Asia. It has found in its introduction to America a climate more congenial to its constitution, and in consequence has very rapidly multiplied, especially in the more southerly countries of that continent. It does not thrive in Sweden in the open air, but requires the warmth of confinement. When only five or six months old, rabbits are capable of breeding; their term of gestation is thirty

or thirty-one days, and a vigorous female will produce about eight young rabbits seven times in the course of a year ; so that in the course of four years her progeny in theory would amount to one million, two hundred and seventy-four thousand, eight hundred and forty individuals. But we cannot average, in the first instance, the amount of fertility at the maximum ; and, secondly, as we observed in the history of the hare, the race is obnoxious to the attacks of men, and of various predaceous animals. If the dam does not find a hole suited to her purpose previously to her bringing forth, she digs one, not in a straight line, but in a zig-zag direction, enlarging the bottom of it every way, and pulling from her own body a quantity of hair, with which she makes a warm and comfortable bed for her young. The female during the two first days seldom if ever quits her young unless when pressed by hunger, at which time she eats with surprising quickness and returns immediately. When she ventures abroad she covers up the hole very carefully, scarcely leaving any perceptible mark of it, and conceals her charge from the male lest he should devour them. She continues these attentions for about a month, when the young are able to provide for themselves. She seeks to avoid all damp places, and prefers a light sandy dry soil to any other. The ordinary term of a rabbit's existence is from seven to ten years. On a dead level it finds it difficult to make its burrow, as, in such a situation, the mould must be thrown upward to the surface ; whereas, on the side of an eminence, the declivity affords a ready fall for the earth. As the rabbits on the island of Sor, near Senegal, do not burrow, we are tempted to suspect that the digging of holes for themselves in colder climates is an acquired art, prompted by circumstances. This conjecture will appear still more probable when we reflect that domestic rabbits never give themselves the trouble of digging, and that when a warren is attempted to be stocked with a domestic breed, they and their offspring remain on the surface, and never begin to make holes for their protection until they have endured many hardships and passed through many generations.

It has been observed by Dr. Darwin, that as rabbits cannot articulate sounds, and are formed into societies living under ground, their method of giving an alarm is very peculiar ; for, when any danger threatens, they thump on the earth with one of their hinder feet, and produce a sound which can be heard by animals near the surface at a considerable distance. The females are the most vigilant sentinels, and remain without till all their companions have entered their holes. These animals are very sensible to any approaching changes of the weather, though habitually concealed under a thick covering of earth, and will seldom go abroad in the day-time unless it be settled and calm ; while their presentiment of a storm in the night-time impels them to rush out and quickly devour their stated fare, that they may be safely housed again before they are overtaken by the blast. It is customary, in stocking a warren, to make artificial burrows, of the diameter of the animal's body, with augers, for defending the rabbits against cold and vermin, till they make holes for themselves. The too great succulence of their diet should be corrected by a due mixture of hard and dry food, such as hay, barley, clover, oats, &c., to prevent scouring, which frequently proves fatal to them : the same precaution will likewise save them from dropsy, a complaint

which they are very subject to. A free circulation of air, and cleanliness, are the best preventives of a pining sickness, accompanied with an infectious itch, to which the young are otherwise liable. A dry regimen will, in general, remove the pustules which sometimes cover their liver ; and fresh air and litter are recommended for a disease in the eyes, which is apt to carry off the females after having suckled their young. As already mentioned, the fur of rabbits is used in the manufacture of hats, for which purpose the grey is usually taken. The lighter-coloured is dressed as fur, and dyed of various colours, in imitation of more valuable skins ; the wool also is sometimes spun for the purpose of being made into gloves and stockings ; but for whatever purpose it is used, it is tender, and therefore very unprofitable to the wearer. The pelt, or skin after the fur has been removed, is of a little more use. It is of small service as leather ; but it can be made into colourless glue of very good quality.

There are many varieties, that is varieties in size and colour, of hares, of which specimens have been brought from different parts of the world ; but it does not appear that there is any great difference in manners, except in so far as these are dependent upon difference of climate and food. We shall therefore give only a brief notice of a few of the more remarkable ones ; and, as generally applicable to them, we may mention that in the warm countries the species which keep more to the hills are more analogous to our hares ; and those which keep more to the low and fertile districts are more analogous to our rabbits.

**BLACK-TAILED HARE** (*L. nigricaudatus*). This species is American, and found in the extensive plains which lie to the northward of Mexico, and between that country and what may be regarded as polar America. The length of the head and body is about twenty-three inches, the head to the ears four inches, and the ears five. "The softness and general appearance of the fur resemble those of a rabbit rather than of a hare. The colouring of the under surface is separated from that of the upper by a distinct line about the middle of the side, which slopes upwards over the haunches to the middle line of the back. Behind this point, the white passing backwards along the middle line becomes more and more blended with black, until the colour of the upper surface of the tail is entirely black. The ears, which are longer than the head, are closely covered with short depressed hairs. These are in front mixed with black and yellow, giving a grizzled appearance ; on the hinder part they are entirely ochraceous for about two-thirds of the length of the ear, the terminal third as well as the tip and the hinder fringe being white, and furnished with much longer hairs. The long hairs fringing the anterior edge are ochraceous, excepting for a short distance immediately below the tip, along which space they are black." The specimen on which the above remarks were made by Mr. Bennett, before the committee of the Zoological Society, was obtained from California, a country of the zoology of which we knew little till lately. The mountainous parts of this country are in general covered with forests, and some of the trees are of immense size ; but still between the coast forests and the ridge of the stony mountains, there are plains of vast extent, on which there are no large trees, though plenty of bushes and herbaceous vegetation. In such places we may naturally expect a great number of rodent animals ; and as the rodentia

of the open fields in North America, and indeed of all the northern hemisphere, are chiefly of the genus *Lepus*, we may be prepared to expect several new species or varieties from this part of America.

THE TOLAI HARE, or SIBERIAN RABBIT (*L. Tolai*). This species is very abundant in the dry plains of Siberia, and in those of central Asia, as far to the southward as the northern slopes of the Himalaya mountains; but in the more southerly latitudes it keeps to the cold and elevated districts. In some particulars of its character it resembles the variable hares of this country, which with climatal differences extend more or less into the northern parts of both continents, and also along the mountain tops farther to the south. But although this species resembles the Alpine, Arctic, or variable hares, in a good many points, it has also no inconsiderable resemblance to the rabbits, and this in the texture of its fur, the form of its body, and its manners. When the Alpine hare is found in such situations as that chase can be given to it, it practices the same doublings and other manœuvres which are practised by common hares. The species under consideration, on the contrary, seeks for some retreat in holes of the earth or crannies of the rock, where its pursuer cannot reach it. Its size is about the same as that of the Alpine hare, and the general proportions of its members are not very different, but its head is straighter, longer, and more compressed. The upper part is mottled with grey and pale brown; the under part of the body is white, and that of the neck yellowish; the legs are yellowish, the tail black above and white on the under side; and the tips of the ears are black. It does not change its colour with the seasons, as is the case with the Alpine hare, but its general tint is paler in winter than in summer.

THE BLACK-NECKED HARE (*L. nigricollis*). This species is very common in the stony and bushy hills of central India; and the Mahrattas call it *Sussuh*, as is supposed from the whisking manner in which it escapes from their sight. The upper part of the body is mottled reddish, the flanks, the thighs, the shoulders, and the rump, mottled with greyish; the tail brownish grey above and white below. The outside of the fore legs, the throat, and breast, are reddish; the top of the head mottled reddish; the sides of the head grey; and the chin and under part of the body white. The ears are white at the bases, reddish in the middle, and blackish brown at the tips. On the nape and upper part of the neck there is a large patch of blackish brown, which extends some way down the back, and also round the sides of the neck, so as to form almost a complete collar. It is about the size of a large rabbit; and, besides being abundant in India, it is plentiful in the eastern islands.

There are numerous other species or varieties found in southern Asia; but they differ from each other chiefly in colour, and the manners of some of them are imperfectly known.

THE EGYPTIAN HARE (*L. Egyptianus*) is about the size of a rabbit, but it has the ears longer in proportion than even the common hare. It is entirely of a fawn colour on the upper part, with very few mottlings; and this colour extends to the breast. The under part is white; the tail black on the upper part; the ears reddish brown with black tips. The eye spot bright fawn colour.

In Southern Africa there are several species, which are, generally speaking, redder in the colour than the

hares of most other parts of the world. The Cape hare is as large as the European one, and has the legs and the ears much longer; it is reddish grey on the upper part and white on the under, with the tips of the ears and the upper part of the tail black. The rock hare of Southern Africa is smaller, and resembles this one in shape; but its colours are much brighter, and in this respect it is usually accounted one of the gayest of the whole family. The sand hare is another species of Southern Africa, but, as its name imports, it inhabits places of a different character from those just mentioned: it has the habits of a rabbit, and is less in size than the rabbits of Europe, but its colours more resemble those of the Cape hares.

THE BRAZILIAN HARE (*L. Braziliensis*) is perhaps the smallest of all the true hares; and it is remarkable for the shortness of its fur, and still more so for that of its tail. In consequence of the almost total obliteration of the last appendage, it has sometimes been called *Lepus ecaudata*, or the tailless hare. Some describers of animals have confounded this with the guinea pig, which is found in the same parts of the world, but the two are perfectly distinct, and this one has the proper form of the hares and rabbits, although, in respect of size, it is a mere miniature. The length from the nose to the tail is about a foot and a half; and the tail, which is round and without produced hair, is about five-sixths of an inch more. The fur on the upper part is blackish brown and fawn, with reddish brown on the top of the head. The cheeks are of a greyish colour, with a light band passing over the eyes; and all the under parts are white. There are some coloured varieties; but the history of the species altogether is not very well made out.

These animals take after the hare rather than the rabbit in their manners. They live in the woods, and are not known in any instance to form burrows in the ground, though they sometimes take shelter in the hollows of trees. Their general habit, however, is to sit on tracks in the open places in the same manner as hares.

THE RAT HARES (*Lagomys*), of which a separate sub-genus is made, do not differ much from the sub-genus *Lepus* in those particulars of structure upon which the characters of genera and sub-genera are usually founded. Their teeth are the same, and so are their feet, in their general structure; but all the feet are more nearly of the same length, much less fitted for leaping, and the animals are much smaller in size. All the known ones are inhabitants of Siberia, where they spend the whole year without any climatal migration worthy of notice. As one means of enabling creatures so feeble, and having their average temperature so high, to exist, these animals have a great disposition to collect magazines of provisions against the time when the surface of a country in which the weather is so severe as it is in Siberia affords them little or nothing. Their principal characters are: the ears proportionally smaller than in the hares; the sub-orbital fosse simple; the clavicle almost perfect, so that they have a cross motion of the fore feet, and can bring them to the mouth something in the same way as squirrels; the furrow in their large incisive teeth of the upper jaw is very distinct, and gives each tooth the appearance of being two; their cheek teeth are only five on each side; their legs are much shorter in proportion than those of the hares and rabbits; and they are altogether a much less important

race of animals. There are at least three species. The common name of all the species in the countries which they inhabit is *Pika*.

**ALPINE PIKA (*L. Alpinus*).** This species has been called the Alpine hare by Pennant and others, so that care must be taken not to confound it with the Alpine hare properly so called. Its general colour is reddish yellow interspersed with much longer hairs of a black colour. The part round the mouth is ash colour, and the under parts of the legs and the ears brown, the latter being rounded in their outlines. The length is only about nine inches and a half.

This species is very abundant in Siberia, where it is well known to the hunters, though Pallas was the first who introduced it properly to the notice of zoologists. It is found on the slopes of the steepest mountains, and even on the most inaccessible rocks; but in all situations they prefer the humid copses, in which, in rocky and mountainous places especially, they find abundance of herbage during the whole of the summer season. They are, strictly speaking, ground animals, and live indiscriminately in burrows excavated by themselves, in holes of the rocks, and in the hollows of decayed trees. They are not gregarious, but are found singly, or in pairs, or in families, according to the season. About the middle of August they begin to collect with great diligence and industry their store of provisions for the winter. This consists indiscriminately of the seeds of plants, of leaves, and of grasses, and they make their magazines in the earth, in the holes of rocks, or in the hollows of trees. These stores are not collected by each animal for itself; for, according to the number that may be in any particular locality, they unite in the labour of collecting the winter store; and it is understood that so true does the collecting instinct remain while the store lasts, that none of those who bore a part in the labour of collecting are ever excluded from their share of the magazine, neither can any stranger invade it, how severely soever necessity may pinch them. These magazines are often of very considerable magnitude, considering the small size of the animals. They frequently bear a considerable resemblance to a hayrick, seven or eight feet high, and about the same in diameter; and when they are of this size, the animals form a subterranean passage from their own dwellings to the store, by which they can find their way when the whole is buried under the snow. These animals do not, as we have hinted, commit any depredations upon the stores of each other, but they often do not come off so well at the hands of the Siberian hunters, who, when provender for their horses fails, often plunder these industrious little creatures.

Pallas examined, with that attention which he was in the habit of paying to all subjects connected with the economy of nature, the stores collected against the season of want by these provident animals. He found that they displayed wonderful animal sagacity, both in the plants which they selected and in the time at which they cut them down. There were no thorny plants or ligneous stems; and the whole appeared to have been cut down at that stage of their growth at which our grasses are understood to make the best hay. If grasses or other plants which are intended for this purpose are cut down too early, they are full of sap, which is not only tasteless, but which ferments and rots the whole when gathered into a heap. On the other hand, if the stems of annual plants stand till the grand labour of

the year is over by the ripening of the seeds, the stems which are left are sapless and afford but little nourishment. The pikas avoid both these extremes, and cut down their winter store when the juice of the stem has acquired its greatest maturity and sweetness. They avoid plants which are in flower; and indeed there are very few warm-blooded animals that will feed upon any plant in the time of its flowering. Pallas adds that, though they are comparatively few, those animals do mix with their more substantial food a few acid plants, or plants which have a pungent flavour of some kind or other, as if it were to give a zest or relish to the rest.

These harmless little animals are not only exposed to the peril of famine by having their stores plundered by the hunters, but they have other enemies besides the human race. The weasel tribe, which are very numerous in that part of the world, seek the abodes of the pikas with much assiduity, and kill them in great numbers; and, as is the case with many of the warm-blooded animals in those northern countries, they are much infested and tormented with the larvæ of insects. Still the destroyers, whether mammalia or insect, appear to be as necessary for the preservation of the animals under consideration as we find most predatory animals are for the preservation of their prey. The powers of life are in all the living productions of nature vigorous beyond the average of the means by which they can be supported. This, it should seem, is necessary for the full play of the system, and the surplus of one race is the means by which some other race is supported; and the wheel goes round till we find the most powerful of the predatory animals becoming, in their turn, the prey of the larvæ of insects apparently the most feeble.

**THE GREY PIKA (*L. ogo-tonna*),** is a native of the same countries. It is of a pale greyish colour on the upper part of the body, with the legs yellowish and the under part white. It is very common in those parts of Siberia which are situated near the lake of Baikal. It is an animal of the desert, or, at all events, of stony places, and does not come near those which man inhabits. Fond of sandy situations. The burrows are dry, shaped after the fashion of those of rabbits, but always with two entrances, and with these near heaps of stones; and in the bottom of these burrows they form for themselves comfortable couches of leaves and other vegetable matters. They are, to a very considerable extent, nocturnal animals, and not only so, but in their nightly excursions they seek the most lonely places. The mountain gulleys, and the narrow strips of land by the banks of rivers, where they are least likely to meet with enemies, are their chosen places; and secure in these, they nibble the fresh bark and buds of the shrubs. In summer they live upon the scanty vegetation which the arid wastes of Siberia produce. As is the case with the former species, they collect stores against the winter; and the people of Siberia look upon them as a kind of "weather-wisers," always concluding that the storm is at hand when those little animals collect their stores with more than ordinary diligence. They do not collect their stores into one great magazine, as is the case with the former species, but into a number of heaps of a hemispherical shape, and about a foot in diameter each, which may be seen near their burrows from about the month of September through the winter: but as the spring approaches

they disappear, and by the time that the snow is off the ground they are nearly gone.

They are very quick and active in their motions ; but they are so timid that they are not easily tamed, and in a state of nature they are so small and feeble that they are exposed to many enemies. During the day they are the victims of birds of prey ; and in the night, the time when in general they are most abroad, they are captured by lynxes, by martens, and by various others of the weasel tribe,

THE CALLING PIKA (*L. pusillus*). This is also a Siberian animal, and it is the smallest of the whole tribe, being only between six and seven inches in length, and weighing between three and four ounces. Its fur is very soft, close, and long,—brindled with brown and grey on the upper part, with the extremities of the feet dull yellow, the under part of the body dirty white, and the breast and lips the same colour but purer. The ears are triangular, and margined and pointed with white. The head is rather larger in proportion than in the other two species, but the animal altogether is very handsome, and its very minute size renders it an object of interest with the curious.

Like the others, it is a social animal, and burrows in the ground. Their burrows are in general deeper than those of the others ; and they are usually formed under bushes or tangled vegetation of some sort or other. During the day they are generally concealed in these subterranean retreats ; but they come abroad during the night, at which time they are understood to see as well as during the day. In the morning and the evening they call to each other with a cry which has been compared to that of the quail, and which, notwithstanding the small size of the animal, may be heard at the distance of more than a mile. It is on this account that the epithet "calling" has been added to their names. The uttering of this cry seems to be a matter of considerable exertion to them ; for it is attended with a motion of the neck and head very similar to those of the dog when he barks. When the weather is fine they are in general silent during the day, but when it lowers, or is tempestuous, they become noisy, and are, like many other animals, a sort of natural indicators of the weather. In the long winters of the country which they inhabit, they form galleries under the snow, by which they reach those shrubs on the bark of which they feed without at all appearing on the surface. In summer they eat grass and succulent leaves ; but they are often reduced to great extremities in the height of summer, when the moisture is dried up and the plants withered from the ground. In such cases they are sometimes reduced to feed on the droppings of the larger herbaceous mammalia ; and they are equally pinched for water, of which they drink freely when it is to be had.

These are very cleanly as well as very delicate little animals, and keep their burrows very neat. They are prolific, the females producing about six on the average. The time of gestation has not been ascertained ; but, from the analogy of the whole race, it is presumed to be very short. The young are produced with the eyes closed and without any fur on their bodies ; but the fur begins to appear about the eighth day, and the growth is very rapid. In their dispositions, these little creatures are the gentlest of all imaginable animals, and though, when in a state of nature, they are very timid, they are very

susceptible to kind usage, and even become very tame.

When awake, the sitting position is nearly spherical, and the animal about fills the hollow of the hand ; but in sleeping, the body is more stretched out. Like hares, they are leaping animals, but the shortness of the hind legs renders the leap rather slow and awkward ; and they are by no means swift animals upon the ground. From the perfect formation of their clavicles, they have a very free cross motion of the fore legs, and can readily bring them to all parts of their heads. They are, indeed, much in the habit of applying the feet to all parts of their fur, which, from its softness and the high temperature of these little animals, offers a very favourite nucleus for insects. One would be very apt to suspect that so small animals would be but ill prepared to bear the rigours of a Siberian winter ; the reverse is however the case. They not only remain in a state of activity during the utmost severity of the inclement season, but maintain when the air is far below freezing a heat of at least 104 or 105 degrees of the common thermometer. Altogether, these miniature hares are very interesting animals ; and they are not the less so, that they are peculiar to a region of the world which is peculiar both in its character and its productions.

HARE-BELLS. Is the *Scilla non scripta* of Linnæus, and one of the most beautiful and common British bulbous plants, growing plentifully in woods. There are two or three varieties of it in gardens.

HARPA (Lamarck ; *Buccinum harpa*, Linnæus). The whole of these beautiful shells were blended in the genus *Buccinum*, by Linnæus, under the name of *B. Harpa*. He appears to have considered them all of one species, but as a more intimate knowledge of malacology enables us to point out distinctive characters hitherto unknown or overlooked, the propriety of constituting a distinct genus of these molluscs becomes apparent, and they well deserve being thus honoured ; indeed it is difficult to reconcile to common sense from what cause the great naturalist jumbled together in his genus *Buccinum*, shells so totally different, even in their form, which was his principal, if not only rule, without we imagine the notch at the base of the aperture to have been his guide in this instance. One general character eminently distinguishes these molluscs, that of having longitudinal parallel ribs, which are compressed, sinuous, and sharp ; the upper extremity of each armed with one or more projecting detached points, giving the spire a coronated appearance ; the form of the shell is oval, more or less inflated ; the aperture, with a notch at the lower end of the canal ; the columella is smooth, flat, and pointed at the base, the last whorl larger than all the others united, the right side deeply excavated. It is doubtful if this mollusc possesses an operculum or not. Lamarck distinguishes eight species of this genus, all of which appear to inhabit the Indian Ocean. One species from the Mauritius has long been distinguished by collectors, in consequence of its relative rarity and very graceful configuration ; it is called the *Harpa imperialis*, and known by the trivial name of the many-ribbed, or many-ridged harp—a name so appropriate that Sowerby adopted it in preference to *H. imperialis* ; but excellent as *H. multicostrata* is, it unfortunately interferes with the established usages of olden time, which have consecrated folly in more than one instance, and we are obliged to bow to custom in

defiance of good sense. This species of harpa is one of the many illustrative proofs of the value attached to every thing of great rarity, and its subsequent depreciation when more abundantly procured; it is within the writer's recollection that fine examples of this shell have been eagerly coveted by amateurs, at prices varying from five guineas to twenty guineas, such as may now be had equally select at three guineas, and such as will, doubtless, be obtainable, at no very distant period, for one-third that sum, or less. This shell is easily recognised from the other harps by the short interval between its periodical additions of growth, which constitute its designation, by forming a greater number of ribs or ridges (the labial terminations of the shell), which seem to indicate a more rapid development of the animal's organic structure than others of the same genus exhibit; this may possibly be accounted for by the local advantages of food or climate, since similar occurrences are observable in other genera of molluscs. Another characteristic distinction exists, that of a small spiral keel running round the summit of this species, which is never the case with others of the genus. The animal of this genus so much resembles that of the *Buccinum*, that its difference is only interesting to the anatomist; and we, therefore, will not here describe it. More than one fossil species of harp is described, but they are not abundant. De Blainville places this genus in the second class, *Paracephalophora*, first order, *Siphonobronchiata*, second family, *Entomostomata*, succeeding the true *Buccinum*, and preceding the *Dolium* and others of the same family.

HARPALIDÆ, or rather HARPALIDES. (See the article CARABIDÆ.) One of the chief divisions into which the great Linnæan genus of coleopterous insects, *Carabus*, has been divided by modern authors, distinguished by having the anterior tibiæ notched near the inner extremity, the elytra rounded at the extremity, the antennæ not elbowed, and the anterior tarsi dilated in the males. This is by far the most extensive group of carabideous (or predaceous land) insects; the species are of an intermediate size, between the larger *Carabi* and the smaller *Brachinides*. They are found upon the ground under stones, decaying leaves, and such like situations; they run with great agility, and many of the species fly well, especially in the hot sunshine. Many of these insects, whose habitations are in obscure situations, are dark coloured, the majority being of a shining black with pitchy or reddish limbs; hence some of the larger species have obtained in some parts of the country the name of black-clocks, and in others imps. Other species, however, which are to be observed constantly running about footpaths, and even upon the pavements in the heart of our metropolis in hot sunny weather, are, as might be expected from such a circumstance, more gaily ornamented, their colours being highly metallic and polished. In their habits they are essentially predaceous, feeding for the most part upon other softer insects, although it appears to be now clearly established (which was not the case when Mr. Stephens published his account of the group in question), that many of the species, chiefly belonging to the genera *Zabrus*, *Amara*, *Curtonotus*, &c., feed, both in the larvæ and perfect states, upon vegetables, the species of the first of these genera being occasionally very injurious to young wheat. The larvæ, which are longish, somewhat cylindric, and furnished with six legs, strong jaws, and a forked

tail, are scaly grubs, having the under surface of the body more fleshy than the upper, and reside in similar situations with the perfect insects, but are very difficult to rear to the beetle state. They feed, like the beetles, upon other larvæ and small insects. Mr. Stephens mentions a curious circumstance connected with these insects, worthy of more minute investigation than has hitherto been given to it. He says, "Many of the species are greatly infested with *Gordius*, a fact so generally known to the 'companions of my youth' that whenever an 'imp' was seen basking in the sun, it was immediately subjected to the ordeal of a pool of water for the purpose of ejecting the 'serpent,' thus called, from his lurking place." Owing to the great extent of the family and the great degree of attention which has been paid to it by the late French entomologists, it has become necessary to divide and subdivide it to a considerable extent, of which some idea may be entertained, when it is stated that this single family, comprising its various sections, genera, and species, occupies nearly three octavo volumes, in the work of the Baron Dejean. In a work like the present, we can of course introduce, and that but shortly, the chief divisions. These are

1. The *Patellinæ*, having the two anterior tarsi of the males dilated, the joints being square or rounded. Genera, *Chlanis*, *Eponis*, *Panagæus*, *Lacinus*, *Badister*, &c.
2. The *Feroniæ*, having the two anterior tarsi of the males dilated, the joints being heart-shaped. Genera, *Sphodrus*, *Calathus*, *Agonum*, *Zabrus*, *Steropus*, *Abax*, *Pocillus*, *Omascus*, &c.
3. The *Harpaliæ*, having the four anterior tarsi of the males dilated. Genera, *Anisodactylus*, *Harpalus*, *Stenolophus*, *Trechus*, &c.

The genus *Harpalus* is very extensive in British species, in which the thorax is quadrate, not punctate throughout, the upper lip entire, with the basal joints of the anterior tarsi of the females not dilated. The type is the *Harpalus ruficornis*, a very common species, generally somewhat more than half an inch long of a pitchy black colour, with the elytra opaque, and the legs and antennæ pitchy red.

HARPAX (Parkinson). A fossil mollusc, described by Parkinson in his *Organic Remains*, and closely resembling the recent genus, *Trigonia*. It certainly belongs to the family *Ostrea*; but scarcely appears to be sufficiently known to pronounce with certainty its rank in modern malacology.

HART'S TONGUE. Is the *Scolopendrium officinarum* of Smith, a common British fern. The *Poly-podium phyllitidis* of Linnæus, another West Indian fern, is also called Hart's tongue.

HAWK (*Astur*), a genus of diurnal birds of prey, nearly allied to the falcons, and of which we shall not need to give a very detailed account, from the notice which we took of the family generally in the article FALCON. They belong to the section which in the days of falconry were called "ignoble hawks," though some of them were trained for sport, and when trained properly, highly esteemed, although they have not the dash and splendour of the long-winged, or noble falcons. One, the gos-hawk, when duly trained, was dignified by the name of the "falcon gentle."

Hawks are pretty numerous, and found in almost every part of the world, though there are some of the species which are not very clearly defined or well made out. They are sometimes designated short-winged, or low-flighted hawks, because in their style

of catching their prey, they do not fly so high, or get through the air with the same splendid action as the long-winged falcons. They are, however, stronger birds in proportion to their linear dimensions; and they are, in some respects, intermediate between the falcons and the eagles. The falcons always strike their prey in the air; the eagles almost as invariably do it on the ground; and the hawks do sometimes the one and sometimes the other, according to circumstances. Some of them fly at a considerable elevation, and beat the ground to considerable distances; but they require a great deal of action and motion of the wings, and have much more "twittering" in their style of flight than the falcons, or even the eagles. In this respect they are perhaps the least graceful of all the diurnal birds of prey; for although they are more bold and powerful than either the buzzards or the kites, they have not the soft wing of the former, or the light fluting and gliding motion of the latter. They are woodland birds, or, at all events, birds of the river and lowland districts, rather than of the upland wilds; and the form of their wings, and indeed the whole of their powers and organisation accord with this.

Their characters are: the tarsi lengthened, so as to be longer than the middle finger toe. The wings short and rounded, and thus better adapted for frequent ascent and descent than for long-continued forward flight. The first quill of the wing is much shorter than the second, and the third is very nearly equal in length to the fourth, which is the longest in the wing. The middle front toe on the foot is longer than any of the side ones; and the claws are very crooked and sharp at the points. They still, however, preserve the true character of birds which kill prey, and eat it in the recent state, in the form of their beaks, which are curved from the base, and more decidedly flesh-cutting beaks than those even of the eagles.

The specific distinctions of hawks are matters of very great intricacy, especially those of countries which are little known, and where, in many instances, a single specimen of the bird is all that has been seen, and that not always by persons capable of forming an accurate judgment respecting it. This difficulty arises, in great part, from the variety of colours to which most birds of prey are subject, at different ages and in different situations. We might expect that in birds which are rapacious, which find their food with considerable labour and exposure to the elements, and which, though discurious in their localities, are not migrant. The general rule we believe is, that as they advance in years they become paler in their colours, and at the same time increase in size and in strength. This is evidently the origin of that altered condition in which the eagle is said to renew its age; for not the eagles only, but all birds of prey, at least all diurnal ones, acquire a different character and plumage at more advanced periods of life than most other birds; and though these are changes and not renewals, each change may be said to be one from greater to greater power in the bird.

As is the case with falcons and eagles, the most powerful hawks are found in the cold latitudes; but they are not so much birds of the mountain, the storm, and the free sky, as the falcons and eagles are. They inhabit chilly countries, where there are woods; and their short wings and facility of ascending and descending, enable them to find their prey in places

where there is no scope either for the stoop of an eagle or the rush of a falcon. Generally speaking, they build more in trees than birds of the two genera which have been mentioned, and between which they are in many respects intermediate. Their bills are not so decidedly notched as those of the falcons; and their claws are more slender in proportion to the length, more curved, and therefore unite a clutching or carrying character along with the killing one.

They admit of subdivision into two sections, which may from the British species, which are the typical ones of the two, be styled Gos-hawks and Sparrow-hawks; and considering the difference between hawks and falcons as we have pointed them out, the gos-hawks may be considered as resembling the ger-falcons, and the sparrow-hawks the common falcons.

The gos-hawks are by much the stronger birds of the two; but they are at the same time heavier, and perhaps not so courageous in proportion to their strength as some of the sparrow-hawks. They have the tarsi short and thick, and covered with shielded scales, and are most abundant in the wooded parts of hills. The sparrow-hawks have the tarsi longer and more slender, and inhabit more the lowland countries, though they also are most abundant in wooded districts.

THE GOS-HAWK (*A. palumbus*) is unquestionably the most of all the hawks; and in those days when hawking was a royal and noble sport, it was much used for low game, that is, game keeping on the ground or near it, such as hares and rabbits, wild ducks, partridges, and other ground birds, which rarely take the sky to any great height. It is longer than the ger-falcon, but the greater length is in the tail-feathers; the wings are considerably shorter and more concave than those of the falcon, and thus it is not seen resting on the air, as is often the case with that bird. It is also less elegant than the peregrine; and after one has seen the flight of falcons, that of even a gos-hawk appears a very inferior and secondary matter. The short hollow wings give it the appearance of getting on with great labour; and though, from the character of its game, which, when winged, is usually shorter winged than itself, it is pretty sure of its prey, it makes but poor work if thrown off at a long-winged bird in forward chase. In consequence of this, powerful as it is, when it comes in the neighbourhood of air-birds, such as swallows, they drive at it in all directions, and so perplex and annoy it, that it turns crooked and sneaks off to the hills or the woods.

The female is, in all the other birds of prey, is by much the fiercer bird. When full grown, the general colour of all the upper parts, the ear-coverts, and a streak continued thence to the shoulder, is blackish brown; the back mottled, the tips of the ear-coverts relieved, and the quills of the wings and tail-feathers edged with faint tints of a reddish brown colour. The space between the nostril and the eye is grey, and the rest of the under part white, with lines of brown and numerous arrow-head spots, which are very obscure on the wing feathers of the legs, and scarcely observable on the vent and under tail-coverts. The tail and tail-feathers are obscure, pointed, and edged with white. Though the colours are not showy, they are very well contrasted. The irides are grey, the naked parts yellow, with a very quick and penetrating eye. In the male bird, the top of the head and the neck is much lighter, and there is a reddish tinge over the greater portion of the body. He

also has fewer spots on the under part, which are generally oval-shaped and much paler. The female is a much superior bird, being better shouldered or winged, and at least a third larger in size. The eggs of the gos-hawk seldom, if ever, exceed four in number. The young are much more of a red colour on

Gos-hawk.

the under parts than the mature birds. They go through a variety of tints of plumage, and, as is generally the case with birds which do that, the standard colour which they at last have is not uniform. The gos-hawk is sometimes nearly white, and at other times tawny, with a few markings, especially the males. This species of hawk, varying in appearance, as is stated to be general with the race, is very extensively distributed over the northern parts both of the eastern continent and of America. It is not found in the extreme north of either; and in the warmer regions it gives place to feebler hawks; but it extends almost to the northern extremity of Europe, to Iceland, and to the Faroe islands. In Asia it does not reach to so high latitudes as it does in Europe; but it extends farther to the south, being common in the hilly parts of China, and still occasionally used by the Chinese in hawking. In England it is so rare, that it can hardly be said to be regularly resident in any part of the country, except, perhaps, some of the wild hilly districts in the north; in Scotland it is more abundant, though even there it is by no means a common bird; and its haunts are local and peculiar. In the rich parts of the lowlands it is hardly known as a resident bird, and rarely seen as a visitant; but in those districts of the Highlands, where remnants of those natural forests which once covered great part of the country are still preserved, there is a greater chance of seeing the gos-hawk. Even there, however, it is to be seen in wild places only; for it shuns the habitations of men, and even the pastures of sheep and cattle. The margins and openings of the woods are its principal places of resort; and its food consists of the smaller mammalia and the larger ground birds. Before the general introduction of sheep into the Scottish uplands, the gos-hawk was more abundant than it is now, and committed very considerable ravages upon the mountain game; and it is doubtful whether the sheep, which certainly do occasionally trample on the nests and break the eggs, may not on the whole be a preserver of grouse on the hills. It may seem singular that a hawk, and a powerful hawk, should avoid places where sheep are pasturing, be-

cause they have neither the disposition nor the power of offering it the smallest injury; but it is a general truth that all birds of prey shun every living creature which does not come within the range of their usual game in its external appearance, and this is one strong proof that such birds seek their prey only by the eye.

There are a vast number of other species, agreeing more or less with the gos-hawk in its principal characters, to be found in various parts of the world, and as far to the south as New Holland, and the extremity of South America. Little is known, however, of their manners, and, so far as these are known, they resemble the manners of the common gos-hawk; and, therefore, the enumeration of them would be a mere list of names, without any interest to the general reader. We shall, however, mention one American species, from the singularity of its common English name.

**THE LAUGHING HAWK (*A. cachinnus*).** This species has the legs and cere yellow; eyelids white; the body variegated with brown and whitish colour. The top of the head is black, and surrounded by a white ring. It is a native of Paraguay, Cayenne, and other parts of South America, haunting those savannahs which are flooded and marshy grounds, and perching on dried and elevated branches of trees, whence it is conjectured to feed on fish, lizards, frogs, and other reptiles. It is rather a stupid bird, occasionally uttering a sound, which is expressed by its vernacular appellation, and, when disturbed, giving a shrill and sudden cry, as though it were laughing. Its manners are much more soft and gentle than those of the gos-hawk; this is indeed a general character of all the birds of prey in the warm regions, and it is worthy of remark as pointing out how nicely the energies and resources of animals are adapted to their places on the globe. A hawk which suits the comparatively warm and uniform climate of tropical America would be but ill adapted for those buffetings by the storm to which such a bird must submit in a northern part of the world; and, on the other hand, the greater strength, spirit, and power of endurance which those northern species possess, would be thrown away upon an animal of warm climates, which would never have occasion to bring them into use. It is in such analogies that we see the beauties of nature, and receive the most irresistible proofs that the whole of it is one in design and in execution, and that perfect knowledge of the whole must have existed on the part of the Author before any part of it was called into existence.

We shall now mention an example of the sparrow-hawks, which differ from the gos-hawks in the manner formerly stated. They are birds of lighter make, more constantly on the wing, much more daring, and do not, as is the case with the others, flit before the progress of cultivation.

**COMMON SPARROW-HAWK (*A. nisus*).** In all the richer and more lowland parts of Britain this species is "the hawk;" or, if any thing additional in the shape of a bird of prey is seen in such places, it is one of the smaller falcons. Like the gos-hawk, the sparrow-hawk is very generally distributed. The male sparrow-hawk weighs about five ounces, and the female about nine; the former measures about a foot in length, the latter about fifteen inches. The bill is bluish, and dusky at the point: the cere yellow; irides bright orange yellow; the plumage of the upper parts, in some of both sexes, are of a deep

bluish grey ; in others brown, edged with brownish red ; the under parts of the female are more fully marked with minute undulated lines of deep brown ; the male is inclined to rust colour on the breast, which in the other is whitish ; on the back of the head, in both sexes, is an obscure broken patch of white ; the quills dusky, barred with black on the outer webs, and spotted with white at the base of the inner ; the tail, like the back, with broad bars of dusky black, the extreme point whitish ; the legs are yellow, long, and slender.

Sparrow Hawk.

The sparrow-hawk is well known for the extent and boldness of its depredations on poultry-yards, and the immense number of birds which it kills and eats in the fields and copses ; but though in boldness, and slightly in its style of flight, it has a trace of resemblance to the smaller falcons, its general nature and habit are totally different. The falcons, if their prey is not killed by the stroke, instantly kill it outright, by breaking the skull or dislocating the neck before they begin to eat ; and this is also known to be the case with the typical eagles ; for, though those eagles which have a strong trace of the vulture in them begin eating their living prey as if it were carrion, the "respectable" eagles never touch theirs with the beak until the gripe of the talons has put an end to its life. The sparrow-hawk has also this habit, and begins to pull feathers and tear away at its prey while that prey is still alive. It is probably on this account that the falconers first drew the distinction between noble and ignoble hawks ; for we associate a degree of cruelty with this mangling and eating of the living animal, which we do not feel when the prey is killed outright before it is eaten ; and there is more than mere sentiment in this distinction, inasmuch as, though death is the final result in both cases, there is a cruelty of a degrading character in death by protracted torture. The female sparrow-hawk builds her nest in lofty trees, ruined castles, elevated rocks, and other places, and she stands accused of sometimes appropriating the deserted nest of the crow, or rather of the rook. The eggs are from four to six in number, of a dull white colour, and sometimes of a bluish tinge, blotched at the large, and sometimes, though very rarely, at the small end, with rust colour. Though it flies low, it

is very fierce and predaceous. It abounds more or less in every quarter of the world, being found as high as Lapland, and in the Faroe Isles, though not, as alleged, in Siberia, and again as far south as Africa. It is common in most of the wooded and inclosed parts of this country, but is of less frequent occurrence in the more champaign districts. It seems to be a partial migrant in some parts of Europe ; for Beton, long ago, witnessed their passage, as Sonnini more recently did, when at sea, between Barbary and Italy. On the approach of winter legions of them move southward, to the dismay of the smaller and weaker migratory birds, on which they prey with cruel assiduity, and from which circumstance the mariners in the Mediterranean give them the appellation of "corsairs." They are stationary in Egypt throughout the year, and many of them are habituated to a town life, usually taking up their residence along with vultures and kites on the terraces of the houses, and sparing, as if by implied contract, the turtle-doves. Indeed, we should remark that, notwithstanding its bold and ravenous propensities, the sparrow-hawk is more easily tamed than most birds of prey, and not unsusceptible of attachment. It is alleged that the young birds are very good eating, and that they are used as food in Egypt. A case of the domestic economy and habits of this species of hawk is so well told by White, in the Natural History of Selborne, that we cannot resist quoting it. "About the 10th of July," says he, "a pair of sparrow-hawks bred in an old crow's nest on a low beech in Selborne Hanger, and as their brood, which was numerous, began to grow up, became so daring and ravenous, that they were a terror to all the dames in the village who had chickens or ducklings under their care. A boy climbed the tree, and found the young so fledged that they all escaped from him, but he discovered that a good house had been kept ; the larder was well stored with provisions, for he brought down a young blackbird, jay, and house-martin, all clean picked, and some half devoured. The old birds had been observed to make sad havoc for some days among the new-flown swallows and martins, which, being but lately out of their nests, had not acquired those powers and command of wing that enabled them, when more mature, to set enemies at defiance."

#### THE MUSICAL SPARROW-HAWK (*A. musicus*).

This is an African species, and it is remarkable as being the only bird of prey that possesses a musical song, or which has a voice at all agreeable to the ear ; for, though there are different sounds among the others, they have little or no modulation, and are generally harsh and screaming. The sound uttered by the goshawk in the breeding season is a slight exception to this, for at that time it utters a sort of whistle ; but though this whistle is clear and piercing, it is not modulated. The song of the present species is, however, described as being sweet. It is given by the male only, as in the singing birds, and during the breeding time ; and, while giving his full melody, the bird is said to be so much absorbed by it as that he may be approached within a few yards. We are not very well acquainted with the whole of the domestic habits of this singular bird ; but Levaillant, who observed it in the woods of the interior of Africa, mentions that, though an exceedingly shy bird at other times, the male may be approached while singing, with the greatest ease, and watched and observed while the song lasts. According to the

same authority, the female bird is particularly grateful for this music; and it is natural that she should, because she, of all the order, is the only female whose mate serenades her with an agreeable song. Some of the owls, indeed, do their best in the way of noise, but there is not much music in their hooting. The female shows her attachment very strongly in the event of the male being shot; while singing is of course the time for doing this; and if it is done, the female instantly flies to the place where the male was perched—for he sings from the perch only—and if she does not spy the body, she continues to fly round and round for a considerable time, uttering the most subdued and mournful cries; and so much is she absorbed by her sorrow, that on these occasions she, too, becomes an easy prey to the fowler. Of course it is only for specimens, to serve the purposes of science or of curiosity, that such birds as these are shot; and where so much attachment is shown among animals, of which our general feeling is so very different, one almost regrets that they should be destroyed for any purposes except the most urgent ones. It does not appear that the male shows so much affection; for, if the female is shot while the male is singing, he continues his song a little, and then flies off. This species is about the size of the peregrine falcon, and more handsomely formed than the common hawks. The general colour on the upper part is grey, with brown undulations on the under part; the quills, which are of a short character, are black; and the tail, which is wedge-shaped, is brown, crossed by bars of white; the form of the wings and tail point out the species as a bird of the woods, where it lodges and nestles, the eggs being four in number, of a white colour, and nearly round. They are bold birds, and commit great depredations on quails, partridges, and other ground birds; they also attack hares and rabbits; and, when other prey is not to be had, they have recourse to mice and reptiles.

THE DWARF SPARROW-HAWK (*A. minutus*). This is also an African species. It is described as being brown on the upper part and white on the under, having the breast marked with longitudinal streaks of brown, and the belly with cross bars of the same colour. Though small in size, not exceeding the common blackbird, this species is daring. It not only drives off the more powerful of the den-tirostral birds, such as the larger butcher-birds, but it attacks the kite and the buzzard. Crows are, however, the most marked objects of its persecution, for it chases them with eager impetuosity, uttering a cry which has been compared to that of the kestrel. The lesser birds are its ordinary food; but when a sufficiency of these cannot be procured, it has recourse to some of the larger sorts of insects, particularly of the mantis and locust tribes. The female, which is nearly double the size of the male, but with plumage of duller tints, forms its nest, in rather a coarse style, of small twigs, intermixed with leaves and moss, and lined with leaves, wool, or moss, and lays in this from four to five eggs. As Levaillant was sitting at a table, engaged in preparing some birds lately killed, one of these hawks suddenly stooped, and, seizing one of the recently-stuffed specimens, and flying to a neighbouring tree, began to pull the feathers, and tear it open, but, finding nothing but moss and cotton, seemed indignant at the disappointment, and at length contented itself with devouring the head, the only part which remained in its natural state.

HAWKMOTH. The English name given to a very extensive primary section of lepidopterous insects which formed one of the three genera into which that order was divided by Linnæus, *Sphinx*, distinguished by a robust body, prismatic antennæ, and strong wings, which do not extend to the extremity of the abdomen. They are generally of a large size, indeed the species found in this country are by far the largest lepidopterous insects which we possess. Their colours are generally agreeably varied, the under wings being often banded. Owing to their strength of wing, their flight is very strong, whence the ordinary English name; during flight, moreover, they produce a strong humming noise, which renders their approach easily perceived. They dart about with the greatest rapidity from flower to flower, preferring those that have long and tubular corollas, into which they introduce their long and spiral tongue, by which they are enabled to reach the honey at its base; whilst thus employed, they remain as it were suspended in the air in front of the flowers, their wings being kept in a long sustained hover. That delightful describer of every thing rural, Miss Mitford, has so well noticed the motions of one of these insects, in her truly national "Our Village," that we are tempted to extract a short passage. She is describing her garden, in which she traces "the gay gambols of the common butterfly as they sport around the dahlias, or watches that rarer moth which the country people, fertile in pretty names, call the bee-bird\* ; that bird-like insect which flutters in the hottest days over the sweetest flowers, inserting its long proboscis into the small tubes of the jasmine, and hovering over the scarlet flowers of the geranium, whose bright colour seems reflected on its own feathery breast; that insect which seems so thoroughly a creature of the air, never at rest, always when feeding self-poised and self-supported, and whose wings in their motion have a sound so deep, so full, so lulling, and so musical; nothing so pleasant as to sit amid that mixture of the flower and the leaf, watching the bee-bird."

The caterpillars of these moths vary considerably in their forms, especially in the anterior part of the body, in some this part is susceptible of great elongation like the trunk of the elephant, whence those species have obtained the name of elephant hawk-moths. This motion is effected when the insect is feeding and in search of food, at which time the neck assumes a narrow conical form, truncated in front, the head and face forming the truncated part; when in repose they withdraw this elongation, so that the front of the body then seems clavate. Other species do not possess this peculiarity, but elevate the anterior part of the body even as far as the first or second pro-legs, assuming an attitude like that of the fabulous sphinx, as represented in our article CATERPILLAR. The last segment but one of the body is furnished with a horn, which varies considerably in form, in some being straight, slender, and smooth, in others, as in the death's-head hawkmoth, being curved and very rugose, whilst in others it is linear and not persistent, existing only during the early stages of the caterpillar's existence, its place being subsequently occupied by a very small eminence. In the sphinx *Hippophaes*, an inhabitant of Dauphiny, the larva,

\* In a note this insect is said to be the *Sphinx ligustri*, or privet hawkmoth, but it is evidently intended for the *Sphinx stellatarum*, or humming-bird hawkmoth.

either to avoid the glare of light or the attacks of enemies, hides itself during the day time beneath the dead leaves lying at the roots of trees, coming forth to feed only at night. The caterpillars of the hawkmoths are smooth, and furnished with sixteen legs, the ten posterior being termed pro-legs; they are of a cylindric form. They live solitarily, and feed upon the leaves of vegetables, eating much at a time and then making a long fast. They are at first very active, and, when approached, fall from the leaf upon which they were placed, suspending themselves by a thread; when more aged they become very sluggish, moving only the head or the hind part of the body. It is in the earth or upon its surface covered with leaves that they undergo the chrysalis state, and make their cocoons, which, however, contain but little silk. In those species which have the proboscis very long in the moth state, the chrysalis is furnished with a curved appendage at its breast, in which the proboscis is rolled up. The chrysalis state generally lasts seven or eight months, but in some species (including the giant *Atropos*) it does not exceed a fortnight. In general there is but one generation during the year, but the humming-bird hawkmoth (*Sph. stellatarum*) is found in the perfect as well as in the larva state from the spring until the first frosts of winter. See, for structural and sectional details, the article SPHINX, as well as those upon the DEATH'S-HEAD HAWKMOTH and DEILEPHILA.

**HAWKWEED** is the *Hieracium Alpinum* of Linnæus, one of an extensive genus of herbaceous plants, common in every dry pasture all over Europe.

**HAWORTHIA** (Duval). An extensive genus of succulent plants, natives of the Cape of Good Hope, and separated from the genus *Aloe* by Duval. The *Haworthias* differ in habit from the generality of the Aloes, and there is also some difference in the form of the corolla.

**HAWTHORN** is the *Cratægus oxyacantha* of Linnæus, one of our common hedge plants, and much admired for the beauty and scent of its flowers. There are several rich coloured varieties in the gardens.

**HEART'S EASE** is the *Viola tricolor* of Linnæus, a common British plant, of which numerous varieties are in the gardens, and now ranked as a florist's flower. See VIOLARIÆ.

**HEART SEED** is the *Cardiospermum corindum* of Linnæus, a genus of climbing plants mostly found in tropical countries.

**HEATH** is the common name of that beautiful family of alpine plants called by botanists *Erica*. They inhabit the northern, and a few of the loftiest hills in the south of Europe; but their grand habitat is on the southern promontory of Africa, where thousands of acres are covered with heaths in incredible numbers, and with hundreds of different species, above six hundred of which are already described.

**HEBENSTREITIA** (Linnæus). A genus of undershrubs indigenous to the Cape of Good Hope. Class and order *Didymia Angiospermia*, and natural order *Verbenaceæ*. Generic character: calyx of one leaf, tubular, emarginate, opening lengthwise below; corolla, a cylindrical tube, limb one four-cleft lip; stamens inserted into the throat of the corolla; filaments short; anthers incumbent and bursting transversely; style filiform; stigma simple; seed-vessel membranaceous, one-celled, two-valved, and two-seeded. Greenhouse plants, and propagated by cuttings.

**HEDERA** (Linnæus). A genus of plants, the

*H. helix* being the well known ivy. There are only three species of the genus as yet in the books; one found in the Canary islands, and another in Jamaica. The British species is found everywhere in woods, and has several remarkable characteristics; though destined to creep on the ground, it steals a permanent support from whatever is higher than itself; thus far it is a parasite, but it extracts no aliment from its supporter. Its embrace, like that of the *Boa*, is sometimes fatal; it is an aspirant as long as there is any thing to surmount, but becomes stationary when it has reached the topmost point. It is indispensable in picturesque scenery; it clothes and supports in its turn the tottering wall. Its berries afford a rich repast to numerous birds, and its melliferous flowers to swarms of insects, and yet its leaves are disrelished by every caterpillar, however voracious, but eaten greedily by sheep, by which, were it not for its climbing tendency, it would be quickly extirpated if approachable by the flock. Sheep suffer, however, for their temerity in denuding the ivy, as it causes a premature shedding of their fleece early in the spring—so say the shepherds. The ivy is sacred to the owl, the wren, and many other birds. There are several varieties, among which the Irish is conspicuous.

**HEDGEHOG** (*Erinaceus*). A very singular genus of insectivorous mammalia, belonging to Cuvier's great order *Carnassier*, and, in the structure of their teeth, the least carnivorous, perhaps, of the whole order. The most striking external character of these animals is the spines with which their bodies are covered, and this has been taken as a popular ground of classification; and the name hedgehog, or urchin (*Herisson* in French), has been applied to other spiny mammalia, such as the porcupines, which are rodentia; to the *Deodin* among fishes; and to the *Echinus*, or sea-egg, which is a zoophyte, belonging to the pedicellated echinodermata. The proper hedgehog, however, belongs to the flesh, or animal-matter eating division of mammalia.

Hedgehog.

This is a very peculiar genus in the structure, in appearance, and in manners; and though the form of their teeth, and various other structural particulars, throw them into different parts of the system, hedgehogs appear, in their general relations to the system of nature, to occupy nearly the same place in the northern countries as the armadillos do in South America; and it is not a little remarkable that two races, adapted for acting a similar part in countries so unlike each other, should both have a hard covering on the upper part of their bodies, though the covering of the armadillos consists of flat plates, and that of the hedgehogs of detached spines.

The generic characters of the hedgehogs are: the cutting-teeth slender, and sharp-edged or emarginated; the canines weak, and shorter than the cutting-teeth, so as scarcely to be distinguishable from the false

grinders ; the grinders are furnished with tuberculated crowns ; the snout produced and pointed, terminating in a cartilage, with an indented appendage, something like the comb of the cock, on the external margin of the nostrils ; the body contracted, and covered with short and strong spines, intermixed with hairs ; the legs short, and furnished with five toes each, armed with digging claws ; the body capable of being rolled up into a ball at the will of the animal, and, when this is done, the spines stand out from it in all directions ; the fore legs are furnished with clavicles, so that they have a cross motion. The females have more than two mammæ, none of which are seated on the breast.

These animals are generally of small size, and obscure and timid in their modes of life. Their principal food is worms, the larvæ of insects, ground mollusca, crickets, and beetles, and sometimes the farinaceous roots of plants. So far as is known, they do not readily attack any warm-blooded animal, and indeed the structure of their mouth is ill adapted for such a purpose ; but they feed greedily upon carrion, and thus assist in clearing the surface of the earth of noxious substances, as well as in destroying vast numbers of those insects which are most eminently injurious to vegetation. Hence they are of considerable service to man ; and as they in general remain perfectly quiet under the hedges, and in other hiding-places, and never do the slightest injury to anything which is of value to the human race, they are productive of good, and not evil, in cultivated countries. Perfectly harmless as they are, however, various charges of wrong-doing have been brought against them. Thus, for instance, some have alleged that they climb fruit-trees, and plunder the fruit by pricking it on their spines ; while others allege, with equal confidence, that they suck the cows, and wound the udders of these animals in a painful manner. We need hardly add that these allegations are not, and cannot be, true ; but they are believed in some parts of the country, and therefore they deserve notice, as belonging to that class of absurd prejudices against animals which cannot too soon be exploded and forgotten.

There is no doubt that the singular form and covering of hedgehogs has been the cause of those charges against them, just as the singular form of the bill of the goat-suckers led to a charge against them of plundering the udders of cattle ; whereas the bill of a goat-sucker is so utterly unfit for such a purpose, that, if we were to fix upon a mouth that could not suck in any way, the very best one to choose would be that of the goat-sucker.

But it generally happens that, while the singular appearance of an animal caused one class of superstitious dreamers to arm it with impossible powers of mischief, another class of the same description of personages was sure to endow it with virtues to which it had as little claim. Pliny, the most laborious compiler of natural history, if not the most correct naturalist among the Romans, gravely asserted that an ointment compounded of the gall of the hedgehog, and the brains of the bat, was the most effective application in the world for removing hairs from any part of the human body where their presence was not wanting ; and thus it appears, that in the matter of personal beauty, the Romans were just as great fools, and, by necessary consequence, as much exposed to the knaveries of quacks, as the

patchers and menders of personal appearance are at the present day. This, however, is by no means the climax of credulity with regard to the wonderful powers of the hedgehog ; for the learned Albertus Magnus, who was not only one of the brightest stars of his age, but had the light of a good deal of true knowledge about him, gravely asserts that an application for the eyes is attainable from this animal superior to all the "Euphrasy and rue" which poets ever sung, or dreamed, or fancied. He says, that if the right eye of a hedgehog is taken, and fried in oil, and applied to the eyes according to the rules of art, and when the stars are in favourable aspect and humour, it will so "purge the visual nerve," that the parties will thence see just as well during the blackest night as during the brightest day. Whether old Albertus, who was on some occasions a wag, as may be seen on perusing his work *De Secretibus*, meant this in irony, is not easy to say ; but it is certain that no application to the human eyes could make diurnal and nocturnal vision alike, except by rendering the former as dark as the latter.

There are only two known species of hedgehog ; the common one, which is found under hedges and in corn-fields in the richer parts of this country, and of Europe generally ; and the long-eared hedgehog, which we believe is chiefly found in northern Asia ; but, though they differ considerably in their appearance and structure, their habits are very much the same. The hedgehog of Europe has twenty-one vertebrae between the last cervical and the sacrum, and fourteen ribs on each side, with the rudiment of a fifteenth one. The long-eared hedgehog, on the other hand, has only nineteen vertebrae between the last cervical and the sacrum, and thirteen ribs on each side, with the rudiment of a fourteenth. Thus there are seven lumbar vertebrae in the common hedgehog, while there are only six in the long-eared one. The angular projection of the lower jaw is longer and straighter in the long-eared one ; the bone of the nose is also longer, and the whole anterior part of the head is more produced. In both animals the vertebrae of the tail, though thirteen in number, are so exceedingly short, that the tail does not appear beyond the buttocks. There seems, indeed, a truncation in the posterior part of these animals which we do not meet with to so great an extent in almost any other. In animals which have the tail developed, and capable of much motion, the spinal marrow extends into that organ ; and active animals, whether they have much power in the tail or not, have the spinal marrow continued as far as the sacrum. But in the hedgehogs the spinal marrow is not continued beyond the seventh dorsal vertebra, so that four of the dorsal and lumbar, and the three sacral vertebrae, merely carry some nervous fasciculi. It is curious that the same deficiency in the posterior part has been found in the toad among reptiles, and in the tetrodon among fishes, both of which animals are deficient of power in the hinder parts of their bodies. Upon the ninth vertebra there is placed a large muscular disc, consisting of concentric fibres, and extending a considerable way over the surface of the animal, and the contraction of those muscular rings brings the body into the form of a ball, and also erect, so that they bristle out in every direction those spines which, when the animal is walking, are more or less directed backwards. Both species of hedgehogs get exceedingly fat toward the winter, which season they pass in a dormant

state. A large portion of this fat collects immediately over, and no doubt protects from the severity of the weather, that muscular disc to which we have alluded as being the organ by means of which the animal rolls itself into a ball. This is a very wise provision of nature, because this circular disc is really the most important muscle in the whole body of the animal. A hedgehog cannot defend itself against even a feeble enemy by active means, neither can it escape by running; and, therefore, its only defence is to present its bristling armour to the enemy; and unless it is put in water, it can remain with its body contracted for a considerable length of time.

Hedgehogs have been represented as inhabiting other parts of the world besides Europe and Asia, as, for instance, an American species has often been alluded to; but, as there are many rodent animals which have their hair or fur intermixed with spines, the probability is, that some of these may have been mistaken for true hedgehogs, for we believe there is no well authenticated instance of any one being found out of the localities to which we have alluded. We shall now very briefly notice the species.

THE COMMON HEDGEHOG (*E. Europæus*). The common hedgehog is about ten inches in length exclusively of the tail, which is not an inch long, and wholly concealed by spines. It is common in most of the temperate parts of Europe and Asia, and found also in some parts of Africa; at least such is stated, but it is, at all events, not numerous in that country. The nose is dusky black, scattered over with a few hairs, and shaped like the nose of a hog, and, like that, adapted for "rooting" or turning up the ground. All the upper parts of the body and the sides are closely covered with strong spines of about an inch in length, very sharp at the points, having the lower part white, the middle black, and the tips white. They are nocturnal, and reside chiefly in woods, fields, and gardens, affecting the roots and decayed trunks of trees, fissures of rocks, and heaps of stones and rubbish that have been gathered in meadows. During the cold season they retire into holes for hibernating, where they wrap themselves up in leaves and moss, and, consequently, dispensing with those stores of provisions which it has been erroneously alleged they lay up for themselves. They are never observed to drink, and they are capable of enduring protracted hunger, even in their most active moments. The hedgehog is mild in its manners, inoffensive and timid; and the more that it is threatened with molestation or danger, the more closely it shelters itself under its coat of prickles. Such is the contractile power of muscle with which it is endowed, that one will sooner be able to tear than uncoil it, unless by plunging it into water, when it swims with considerable ease. Though this little harmless creature is not insensible to pain, it has been known to undergo the cruel process of vivisection without a single groan. It is said that foxes contrive to coax the hedgehogs out of the defence of their armour, in order to devour them; but we are not aware that any one ever saw this put in practice; and therefore, the probability is, that it belongs to that class of gratuitous instances of cunning which have been so copiously ascribed to the fox. The boldest of the dogs, even the bull-dog, which will attack the most powerful enemy, and persevere to the death, can make very little of the hedgehog. There have been instances in which dogs of this species have laid hold of the animals and

shaken them till the muscles relaxed, and the covering was contracted on the back; but no sooner did this take place, and it happened only when the dog had thrown the animal so that it alighted on the ground, than the protecting armour was again contracted; and the dog, in attempting to seize the animal a second time, had his mouth so much lacerated with the spines as to be covered with blood, and he was ultimately forced to give up attempting to bite the hedgehog, and confine his attack to barking at it, which is not an uncommon habit with dogs, and they appear thereby to attempt frightening that which they cannot conquer. It is, in all probability, upon this principle that dogs which are cowardly in fight are always the most given to barking.

During the day, hedgehogs never move about, unless compelled by some accident; at this time they rest in holes of the earth, at the roots of bushes, under leaves, or in grass or other tall herbage, which affords them protection; and while thus reposing they are always rolled up. In consequence of this habitual retirement and repose during the day, they are less frequent to be seen in proportion to their numbers than perhaps any other animals; and therefore, even to the country people, in those districts where they are most abundant, a hedgehog is so seldom seen, that when the rustics get hold of one they hardly know what to do with it. A case occurred recently in one of the southern counties of England, which shows upon how slender grounds the name of being learned may be acquired among such people; and also how readily a mere name, which really has no meaning whatever, is sometimes accepted as a substitute for knowledge. Some rustics engaged at haymaking or harvest work, it matters not which, found a hedgehog snugly rolled up in its spherical form, and so bristled over with spines that even their hard hands could not touch it with impunity. What it was they were utterly at a loss to determine; but at length one old woman mentioned that her Joe had been three weeks at a Sunday school, was "larned" in consequence, and she was sure he could help them in their perplexity. The rustic scholar was sent for, and surveyed the hedgehog with as widely wondering eyes and mouth as it had been surveyed by any of the others; and while he did this the group waited as wistfully for his response as the ancients did for those of the Delphic oracle. Having finished his survey, he declared, in the most solemn manner, "I'm sarten it's a *summat*." "There now," said the exulting mother, "didn't I know as Joe wart gy'un a *neame*." The name was perfectly satisfactory to the audience; and the simple youth was at once elevated to the rank of village philosopher; and it is not improbable that in more pretending classes, philosophic honours have sometimes been acquired on grounds not substantially differing very much from those above stated; and therefore the naming of the hedgehog contains a good moral, if we only knew how to bring it out.

The whole covering of the hedgehog does not consist of spines, for under them there is a close and curly fur; and it seems as though the insect world took vengeance upon an animal which destroys so many of their race, for the fur of the hedgehog is very much infested with ticks, which are as large as those that inhabit the fur of the dog; and the animal appears to have no means of getting rid of them but by taking to the water, in which it can swim with considerable ease. The muzzle, the borders of the

lips, the eyes, and the under sides of the feet are, however, always naked; and so is the tail and the mammae of the female, of which there are five pairs. In the eyes there is a third eyelid, which can be produced so as to cover the eye, as in the cat. The eye and optic nerve are both very small, and therefore we may conclude that the sight of these animals is very weak. Hedgehogs which have been kept in a state of confinement (for they are very easily tamed, and when so, remarkably gentle) have given abundant proofs of this, by showing little excitement when objects of sight approach them. Their scent appears, on the other hand, to be very acute, for they keep constantly turning up their noses, moving the cartilaginous appendage, and apparently snuffing the wind in the same manner as pigs do. They swim much faster than they walk on the ground. Some tame ones have been brought to subsist wholly on milk and vegetable matter; but it is probable that, in a state of nature, they are very carnivorous. Some have alleged that they occasionally kill rabbits for the purpose of eating them, but, though a rabbit is more easily killed than almost any animal, this is somewhat doubtful. It is certain, however, that they eat very greedily the carrion of rabbits, hares, dogs, and other animals; and it is said that they contrive to break open the skull and eat the brain of the animal before they touch the flesh; and this is physiologically considered as being the most carnivorous trait in the character of any animal whatever.

They bring forth about the end of spring, and the young vary from three to seven. They are white at their birth, and the points of the spines are rarely perceptible through the cuticle. Hedgehogs are frequently introduced into houses for the purpose of expelling the *blatte*, or cockroaches, which they pursue and devour with great eagerness. The Calmuc Tartars keep them in their huts in place of cats. Some years ago, a man exhibited in the Champs Elysées, at Paris, a large boxful of hedgehogs, which not only unrolled themselves, but allowed themselves to be handled and teased at his orders. There are other instances recorded of individuals of this species having been completely domesticated. The skin of the hedgehog was used by the ancients as a clothes-brush; and it is applied in some countries to the muzzle of calves which are to be weaned. Though the flesh of this animal is generally despised as food, the Spaniards are said to value it very much in Lent.

The hedgehog, considered altogether, is one of the most singular animals found in European countries. It is met with only in climates which are comparatively temperate, not occurring in high latitudes or at a great elevation upon the mountains; and even in those rich parts which constitute its proper localities, it retires under ground in the winter. Its temperature is indeed low, and its circulation sluggish at all seasons of the year, and it seems equally incapable of bearing extremes of heat, light, and cold, without passing into a dormant state. Though it is generally stated to extend into Asia, and even into the north of Africa, those statements are at best doubtful; and it is probable that the spiny animals of insectivorous habits which are found there are different species, or at all events different varieties, from our hedgehogs.

THE LONG-EARED HEDGEHOG (*E. auritus*). This species, in all its localities, is smaller than the European hedgehog; and it is at once distinguished from that by longitudinal furrows in the spines, which are

channelled longitudinally, and have the margins of the channels marked with little knots or tubercles. These spines are not either so long or so formidable as those of the European hedgehog; and therefore they form a much less complete defence to the animal. They are further distinguished by the shortness of their upper incisive teeth, and the length of their lower ones; by a tuft of long soft hair at the angle of the gape; and, above all, the greater length of their ears, from which they receive their names. The upper part of the body is covered with slender brown spines, with a whitish ring at their base, and a yellowish one at the point. They are not joined in tufts or shafts at their extremity to the root, but separated singly, and are smoothed back when the animal is in a state of repose. The nostrils are denticulated like the crest of a cock. The limbs are longer and more slender than those of our European hedgehog. The tail is conical shaped, almost naked, and rather shorter than the common species, and the hair is in general much finer; in the limbs and belly it forms a fine whitish hair; the muzzle is furnished with four rows of whiskers; the tail is of a yellowish white colour; the iris of the eye bluish. The female has usually two litters in the year, and brings forth from six to seven at a birth. It hibernates in holes a few inches below the surface of the ground. It feeds on insects, and can eat with impunity cantharides, and others which are so acrid and poisonous in their nature as that they blister the skin of the human body, and are attended with very serious effects if administered inwardly, unless in the most minute doses imaginable; and they also occasion the greatest uneasiness and pain to digitigrade mammalia, if these happen to swallow them. This is a singular distinction between the stomachs of at least some of the insectivorous carnassiers and of those which are more decidedly carnivorous. It has been said that bears can take with impunity doses of prussic acid which would be sufficient to kill a whole den of lions; and it is certain that even if one of those poisonous beetles upon which the hedgehogs feed habitually were to be swallowed by a strong dog, it would throw him into convulsions. This is perhaps one of the most wonderful instances which we have of the adaptation of animals to the nature of their food; and it is not wholly confined to the insectivorous and other plantigrade carnassiers, but is found to a certain extent in hogs, and may exist also in other pachydermata. Even among ruminant animals there are remarkable differences in this respect, for goats can eat plants which would produce the rot in sheep, and be of the most serious injury to oxen. This, however, is a department of animal physiology which is very obscure in itself, and has been very little studied; but it is at the same time one well deserving the attention of physiologists. In the case of the hedgehog, the powers of the stomach are as well adapted as its teeth for insect food, and for such insects even as are destructive to others differently adapted; if it were otherwise, its mental impulse and its physical capacities would frequently induce its destruction. This species closely resembles the European one in all its manners and habits; and towards the close of autumn it gets remarkably fat.

It is probable that those who have described the common hedgehog as being found out of Europe have confounded it with this species. On the other hand, it does not appear that this one has ever occurred in Europe, or in Africa, except in those parts which are

nearest to Asia. Hedgehogs, from their structure and the slowness of their motions, are not at all adapted for migration; and therefore we may not only expect that every species will keep closely to its locality, but that they must be considerably affected by the average character of the ear in that locality. In southern Africa, in Australia, and in the American continent, there are certainly none, for the spiny mammalia there belong either to the rodentia or the edentata. Hence the pendent-eared hedgehog of the East, the earless hedgehog of America, and some other varieties which have been founded upon mutilated specimens, cannot be received into this genus. The one of the Eastern Islands and that of America are rodent animals, approaching to the porcupines in some of their characters; and though some of the others feed on insects, none of them are carnivassiers in the structure of the teeth.

**HEDGE HYSSOP.** Is the *Gratiola officinalis* of Linnæus, a medicinal plant belonging to the natural order *Scrophularinæ*, an herb indigenous to Europe.

**HEDYCHIUM** (Konig). A beautiful genus of East Indian plants, belonging to the first class and order of Linnæus, and to the natural order *Scitamineæ*. Generic character: calyx tubular; corolla of one petal, tubular; limb in six parts, turned back, middle lobe cut; stamens, filaments filiform and jointed; anthers terminal; style filiform; stigma funnel-shaped; capsule aggregate. This is a favourite genus of stove plants, requiring large pots, and a lofty house to flower in. They are increased by dividing the roots.

**HEDYOTIS** (Willdenow), or Indian madder, is a genus of annual and perennial plants, natives of India and other places. The *H. diffusa* was called *Oldenlandia diffusa* by Roxburgh; and Fischer found one in Russia, which he called *Oldenlandia ramosissima*. They belong to *Rubiaceæ*.

**HEDYSARUM** (Linnæus). A very extensive genus of annual, biennial, and perennial herbs, chiefly natives of Europe. The flowers are diadelphous, and consequently belong to the natural order *Leguminosæ*. This genus was formerly much more extensive than it now is, several new genera being taken from it. It comprises some highly ornamental, and a few elegant plants, admitted into the flower-garden, where they are easily increased.

**HEISTERIA** (Linnæus), is the *Bois Perdrix* or *H. coccinea* of Jacquin: a large West India tree belonging to the *Olacineæ*.

**HELENIUM** (Linnæus), a North American genus of annual and perennial herbs, belonging to *Compositæ*. They are tall growing plants, and are usually introduced among shrubs at some distance from the walk. They are increased by division.

**HELIANTHEMUM** (Tournefort), a very numerous genus of herbaceous undershrubs, and shrubby or creeping plants, chiefly European. They belong to the *Cistineæ*, and are cultivated as ornamental plants. The American species require the protection of a greenhouse or frame during winter: the European ones grow on rock-work or on the common borders.

**HELIANTHUS** (Linnæus). Annual and perennial herbs, originally discovered in America. The sunflower is in everybody's garden; and, from its large flaming yellow flowers, is universally known. It has often been affirmed, though there is rather more of poetry than truth in the assertion, that this plant is so completely identified with the luminary from whence it derives its name, that it regularly and

progressively follows its course. It is true that the "golden rayed flower" does, to a certain extent, revolve on its stem, but it is a popular error to suppose that it keeps a measured pace with the sun. The *H. tuberosus* is a culinary vegetable, cultivated in every garden, and plentiful in our markets. The Italians call this plant *Girasole artichocco*, of which our vulgar name "Jerusalem artichoke" is a vile corruption. The seeds of the common one, *H. annuus*, are very nutritious food for poultry; and in North America they are made into cakes by the Indians, and from them an excellent oil is extracted. The pith of the sunflower consists of pure medullion.

**HELICARION** (De Ferussac). A genus of shells, now united with that of *Helicelimax*, from which it differs so slightly as not to require a separation.

**HELICELLA** (Lamarck). A genus now united to that of *Helix*, of which it forms a species.

**HELICHRYSUM** (Persoon). A splendid genus of ornamental undershrubs, chiefly natives of Africa. Class and order *Syngenesia superflua*, and natural order *Compositæ*. Generic character: anthodium scaled, the inner scales are furrowed and rayed; receptacle naked. This genus was formerly included among the *Gnaphaliums*, but separated therefrom by Mr. D. Don and others. They are handsome greenhouse plants, thrive well in moor-earth mixed with loam, and cuttings placed in the same soil take root readily. Some of the species ripen seed.

**HELICINA** (Lamarck). The general structure of these molluscs greatly resembles that of the genus *Nirita*; but they are terrestrial, some feeding on trees and others on the surface of the earth: from the helix they may easily be distinguished by the transverse callous columella, depressed and diminished in thickness at the lower part; the shell sub-globular, not umbilicated; opening semi-elliptical and entire, with a sharp edge, forming an angle at the lower part of the side, with a horny operculum. The *Trochus vistarius* of Linnæus might easily be confounded with this genus; but its being a marine shell, and the callosity covering the whole of its lower surface, by which it is rendered convex, sufficiently distinguish it from the *Helicina*.

**HELICONIA** (Linnæus). A genus of large leaved herbs, natives of South America. Class and order *Pentandria Monogynia*, and natural order *Musaceæ*. Generic character: flowers included in coloured spathas; partial flowers in bundles; corolla six-cleft; the exterior clefts two-lipped and revolute; the inner convolute; stamens inserted into the base of the corolla; ordinary number six, but part of them often abortive; filaments awl-shaped and erect; anthers linear; style three-sided; stigma obtuse; capsule oblong, three-sided, three-celled, and full of seeds. The heliconias are stove plants, and require rich soil, ample space, and a strong heat to flower them in perfection.

**HELICTRES** (Linnæus). This is the Screw Tree of the East and West Indies. Class and order *Monodelphia Dodecandria*, and natural order *Bombacææ*. These plants grow and flower freely in our stoves, and are propagated by cuttings.

**HELIOCANTHARUS** (MacLeay). A genus of coleopterous insects, belonging to the subsection of *Lamellicornes*, and having for its types the sacred beetles of the Egyptians (*Ateuchus Egyptiorum*, Latreille, *Scarabæus Sacer*, Linnæus, &c.), having the front of the head divided by notches

into rays, the lateral margins of the elytra entire, the anterior tarsi obsolete, and the four posterior legs long and ciliated, &c. These insects are nearly allied, both in structure and habits, to the genus *Gymnopleurus* (which see), depositing their eggs in balls of dung, which they roll into holes prepared for their reception under ground. Mr. MacLeay has described fifteen species of this group in the *Horæ Entomologicæ*.

Perhaps there are no insects which have attracted so much celebrity as those now under consideration, and which were, amongst the many objects "*qualia demens Ægyptus coluit*," under the name of the beetles of the sun. Amongst the Egyptians, and other nations in friendly intercourse with them, these insects were objects of especial regard; and when we remember the singular character of the Egyptian speculations, and the great interest which attaches to the hieroglyphical discoveries of the present day, we are induced to inquire into the causes which could have led this celebrated people to attach so much importance to a comparatively insignificant creature like the heliocantharus.

Apollonius, in his work upon the symbolical wisdom of the ancients, has entered largely into this subject, describing three species of scarabæus; the first or the real scarabæus, or beetle of the sun presented several rays from the head, whence it was consecrated to the deity of the sun; and it was supposed that all the individuals of this beetle were of the male sex, and when one of them felt an inclination to continue its species, it sought out the dung of a cow, of which it composed a ball representing the globe. This ball it propels backwards with its hind legs, the insect looking at the same time in the opposite direction; and hence they come to be regarded as emblems of the sun, which appears to proceed through the heavens in a course contrary to that of the signs of the zodiac; and as these scarabæi were supposed to roll their balls in the direction towards the west, their own motion or at least their heads being directed towards the east, it was further supposed that the first of these motions was a symbolical exhibition of the diurnal, the second of the annual, motion of the earth and planets. Moreover, these male scarabæi were supposed to roll their balls from sunrise to sunset every day, for twenty-eight successive days, after which they buried them in the earth, in which they were supposed to conceal themselves for twenty-eight days, being the duration of a lunar revolution, and during which time the race of the scarabæi was supposed to be animated. On the twenty-ninth day, which the insect knows to be that of the conjunction of the moon with the sun, and of the birth of the world, it opens its ball, from which a fresh race of scarabæi make their appearance, casting the fragments into the water. For these fanciful and erroneous reasons, the Egyptians, anxious to delineate a being engendered by itself—selected the scarabæus. The second species has two horns upon its head like those of a bull, and was consecrated to the moon, that goddess of whom the heavenly bull, according to the Egyptians, was a type. The third species had but a single horn, and was of a different form. This, as well as the sacred ibis, was supposed to be consecrated to Mercury. Apollonius also mentions that the figure of a blind scarabæus was emblematical of the death of a person who had perished from a fever occasioned by the excessive heat of the sun.

The first of these species is considered by Latreille in a valuable memoir upon the sacred insects of the Egyptians, to be that insect which he has described under the name of the *Ateuchus Ægyptiorum*, and

*Ateuchus Ægyptiorum.*

which, having a metallic greenish tint, and being of a larger size, is supposed by him to have attracted the attention of this people, rather than the other species, which are uniformly black. Moreover, the former is only found in Nubia and Ethiopia, which were the portions of the continent of Africa supposed to have been first inhabited by the Egyptians. On coming more northward, however, other species are found, which, occupying the station of the former, necessarily became objects of a similar veneration. Latreille, was only able to find figures of the former on the mummies opened in his presence. The second species mentioned by Apollonius appears to be a species of *Copris*, or *Typhæus*, resembling our common English bull comber (*Typhæus vulgaris*); and the third is probably a species of the former genus, allied to our *Copris lunaris*.

As objects of worship these insects were sculptured with great skill, but the figures which have been discovered exhibit so many varieties, so much disfigured by the caprice of the artist, that the determination of many of them must be very doubtful; still their effigies must certainly have had the effect of recalling to mind the systems of cosmogony and mythology established by this extraordinary race of men. Harbingers of spring, and the types of fecundity, announcing by their reproduction the renewing of nature; singular from their instinct and forms, and occupied unceasingly like Sisyphus of old in rolling their balls along, it is not surprising that these insects offered to the priests of Egypt an emblem of the works of Osiris or the Sun. And it was not sufficient for their superstition that they should be found in every temple, upon the bas reliefs and capitals of columns, and upon obelisks, they were engraved with other hieroglyphical figures upon different kinds of stone, and fashioned into medallions of carved cornelian, engraved upon split pearls, pierced in order to form necklaces, as well as for rings and seals. The image of this tutelary deity followed the Egyptians, and descended with them to the tomb, small models of the scarabæi being usually placed in the chests of their sarcophagi; and one of these, mentioned in Greaves' "*Pyramidographia*," was formed of a magnet, which, although three thousand years had elapsed since it was taken from the rock, its natural bed, still retained its magnetic virtue. Sometimes even the insects themselves were put in the coffin; and on some of the mummies lately opened in this country, small

models of the insects have been found close to the body, folded under many layers of bandages.

The most precious metals were often employed in the construction of these models, in the place of marble or granite, and oftentimes the gigantic views of the Egyptians induced them to carve colossal statues of them. One of such colossal figures cut out of black granite is to be seen in the saloon of the gallery of the Elgin marbles at the British Museum, and which is so large that the writer could scarcely sit comfortably astride upon its back. This statue is known amongst entomologists by the name of Bonelli's horse; and as the anecdote relates to two distinguished entomologists, and has not hitherto appeared in print, we may be excused for occupying the attention of our readers a moment with it. When the late celebrated Italian professor Bonelli was in England, he was shown the various contents of the British Museum, and on arriving at this statue, the equally celebrated naturalist who accompanied him, and who at that period presided over the zoological department of the establishment, jocosely invited him to mount the sun-beetle, which, from his diminutive size, his friend thought he would not be able to accomplish. He, however, succeeded with difficulty, and since that time the statue has acquired the name mentioned above.

We may in a great measure account for the discovery of so many of the models of the sacred beetles in mummies and sarcophagi, by recollecting that the habits of the insect would forcibly exhibit the phenomena of resurrection; and it is to this idea that Mr. Moore alludes in that fanciful work, "The Epicurean," in which he describes an Egyptian chapel, the walls of which were ornamented with the various symbols, by which the mystic wisdom of the Egyptian loves to shadow out the history of the soul, including "the Theban beetle as he comes forth after the waters have passed away, and the first sunbeam falls upon his regenerated wings," adding the following note from M. Jomard, "On voit en Egypte après la retraite du Nil et la fécondation des terres, le limon couvert d'une multitude de Scarabées. Un pareil phénomène a dû sembler aux Egyptiens le plus propre à peindre une nouvelle existence." And in the writings of St. Ambrose, the Messiah is frequently compared to a scarabæus, without any notice of the cause for such a strange comparison, although it evidently has partly originated in the supposed resurrection of the insect from the mud left by the retiring Nile, and partly in a still more fanciful reason for the application of this emblem to Christ, quoted by Moore from St. Augustine: "Bonus ille scarabæus meus, non eâ tantum de causâ quod unigenitus, quod ipsemet sui auctor mortalium speciem indiceret sed quod in hoc nostrâ fæce sese volutaverit et ex hac ipsa nasci voluerit."

Many others were the superstitions connected with these insects entertained by the Egyptians, which it would occupy far too much space to detail. It is far more pleasant and refreshing to look at nature as she really is; and in observing the proceedings of the *Heliocantharus*, we not only find a most interesting instance of that instinct which induces the female to secure a fit retreat for her progeny, but also perceive the great share which these insects, like the *Geotrupes*, take in the general economy of nature, in places where they abound, as in Egypt. A recent author thus describes the proceedings of one of the species, in the last number of the Entomological Magazine: "*Ateuchus variolosus* flies always in the middle and

heat of the day. It walks backwards with its pellets, in which it buries its eggs, and which are generally made of asses' dung. The pellet is about an inch and a half or two inches in diameter, and in rolling it they stand almost on their heads with their backs to it, guiding it with their hind feet, and occasionally mounting to the top when they find difficulty in urging it on, probably to destroy its equilibrium. Its wedge-shaped and dentated clypeus gives it strong mechanical powers in removing obstacles, and as I frequently found it buried under stones, in looking for *Carabi*, we may remark the wisdom of Providence in furnishing it with a lever to raise such heavy weights."

**HELIOPSIS** (Persoon). Annual and perennial herbs of America, nearly related to *Bupthalmum*, and belonging to the natural order *Compositæ*.

**HELIOTROPIUM** (Linnæus). Herbs and undershrubs, natives of the warmer parts of the world, and belonging to the natural order *Boraginææ*. The *Heliotropes* or *Turnsoles* have long been cultivated favourites, in consequence of the fragrance of some of the species. The *H. Peruvianum* is seen in almost every cottage.

**HELIX** (Linnæus, and modern naturalists). The common garden snail at once illustrates the characters of this genus, properly so called, though Linnæus, under that designation, had blended together, in the strangest disorder, land, marine, and freshwater molluscs, so intermingled both with regard to the habitat and functions of the animal, and the form and character of the shell itself, that the naturalist sought in vain for those concurring testimonies and distinguishing generic types, by which alone his mind could be guided in the propriety of adopting one system of classification in preference to another. Lamarek first ventured to depart from the arrangement of Linnæus with respect to this genus, and at once separated from the *Helices* the genera *Auricula*, *Caracalla*, *Cyclostoma*, *Planorbis*, *Achatina*, *Anastoma*, *Bulinus*, *Janthina*, *Paludina*, *Pupa*, *Ampullaria*, *Lymnæa*, *Succinea*, *Sigaretus*, some of the *Natica* and others, each possessing consistent, natural, and well-marked generic distinctions, sufficiently important to authorise their separation from the incongruous mass in which they had been confounded. Shells of the genus *Helix*, as it is now constituted, are all of them terrestrial, and their families innumerable; all parts of the globe not actually covered with water affording nourishment to the immense variety of different species which every where abound in the hottest as well as the coldest climates.

Their number and beauty can only be equalled by some families of the insect tribes, in which a similar extent of species is observable. We have already, under the article *CONCHOLOGY*, endeavoured to bespeak some compassion towards this much persecuted but useful animal, and will, therefore, only repeat the unanswerable conclusion, that where great reproductive powers, or a strong tenacity of life, exist in any class of the Almighty's creatures, great ends are to be worked by their agency, however humble their powers may appear to that most self-sufficient of all animals—man: a conviction of this is forced upon him even by the snail, would he but once condescend to examine the good services it renders mankind, upon the broad principle of universal benefit, dismissing narrow-minded prejudice, selfish interest, and ignorant cruelty. He would then hail this little creature as a benefactor to society, and its presence

would no longer be the signal for its barbarous destruction. The genus *Helix*, as it now stands established according to the modern school of naturalists, comprehends such of the shells, so called by Linnæus, as present the following constant and similar generic characters in all their species, namely, their being orbicular, convex, or conoid, generally globular; aperture entire, of a greater width than length, very oblique, contiguous to the axes of the shell, having the margin of it disunited by the angle of the previous evolution or whorl; the lip constantly thickened or reflected inwards, a circumstance which never takes place in marine or fresh-water shells, whose general appearance, in other respects, might resemble that of the *Helix*. The summit is always rounded and smooth, never turrulated, as in some very similar molluscs; the substance of the shell is never pearly, though externally and internally highly polished.

The animal is so constantly under our convenient observation, that it need not be here minutely described; and it affords so much instruction in the formation of shells generally, that we earnestly invite the young naturalist to walk abroad and seek from a snail that practical information which volumes might fail to convey so clearly or so satisfactorily.

During the heat of the day these animals conceal themselves in moist shady places, and during winter they hybernate in the holes of trees and walls, and not unfrequently beneath the surface of the ground; some of them closing the aperture of their shell with a false or temporary operculum, protecting them from enemies and the change of temperature while they remain in that inactive or torpid state. Some instances have been pointed out already, in the article CONCHOLGY, of the tenacity of this animal's life, and we need only add, that we believe it to be a well-attested fact, that a portion, or even the whole, of its head will be reproduced after having been severed from the body by accident or philosophical cruelty.

Being ourselves so much indebted to the snail for unravelling some of the apparently mysterious operations of nature in this branch of natural history, we cannot quit this article without trespassing a short time longer on the space allotted to our subject, a circumstance we have constant reason to regret, though it is our anxious wish to compress every useful information into the least possible compass. Should any doubt yet linger in the naturalist's mind of the propriety of adopting the system of modern malacology, founded as it is upon the organisation of the animals constructing and inhabiting a testaceous covering, in preference to that of former schools, in which the capricious shape of the shell solely guided the formation of their genera, let him examine the labours of the snail and judge for himself—he will there meet with such unanswerable evidence of the wisdom of deserting his old prejudices, that it would be palpably absurd still to adhere to them when another course is pointed out to him by Nature herself. In every case the study of nature would be greatly facilitated by observing more narrowly the indications she furnishes for a correct classification of distinct genera and species, which are but too frequently considered of little value, or altogether overlooked from being often but slightly defined; they are, nevertheless, of the utmost importance, and enable us to judge by analogy of that which we cannot in most cases confirm by actual observation, since the habits

of molluscs are so little known and so difficult to examine.

From the extremely numerous species of this genus, all naturalists have agreed upon the necessity of forming certain sub-divisions to facilitate a knowledge of the species. De Montfort pointed out several, Oken proposed others, and many other writers have done the same; but the Baron de Ferrussac has the most effectively occupied himself with this group of molluscs, and pointed out, to our thinking, the best and the most natural arrangement of the genus *Helix*. To his splendid publication, therefore, we must refer our readers for that minute detail we cannot here give at length, and will not be unjust enough to mutilate by abbreviation. Of the genus but few are known in a fossil state, and perhaps not more than three analogous to recent examples. A reference to the article FOSSIL will satisfactorily explain this fact, we will, therefore, conclude with observing that the genus *Helix* occupies a most important station in the economy of nature, and is well worth a much more serious contemplation than has hitherto been bestowed upon it, as it is one which will eventually conduce to beneficial results as yet but little known, particularly in this country, where snails are considered as common pests, and exterminated with inveterate diligence. The Linnæan genus *Helix* now forms the family *Limacina* of modern writers.

**HELLEBORUS** (Linnæus). A genus of European herbs, particularly well known for their imputed poisonous qualities. Class and order *Polyandria Polygynia*, and natural order *Ranunculaceæ*. Some of them are early flowerers; hence one is called the Christmas rose. The whole are accounted violent drastic purgatives, and in large doses dangerous. They are mostly now laid aside, and with reason, as when incautiously administered as anthelmintics death has ensued. The *H. orientalis* grows plentifully on Mount Athos at Delphi, and on the Bithynian Olympus.

**HELLENIA** (Willdenow). A genus of perennial herbs found in New Holland and China, belonging to the first class and order of Linnæus, and to the natural order *Scitamineæ*.

**HELONIAS** (Linnæus). North American herbaceous perennials, belonging to the sixth class of Linnæus, and natural order *Melanthaceæ*. These plants are hardy, and affect a peat soil and moist situation. They are increased by division or seeds.

**HELOPHILUS** (Meigen). A genus of dipterous insects, belonging to the section *Athericera* and family *Syrphidæ*, having the body rather long and nearly smooth, the hind thighs large, thickened, and finely toothed, the face impressed below the antennæ, and the wings not carried horizontally when at rest. These are large flies, nearly allied to *ERISTALIS* (which see), being however much fewer in number of species, the type being the *Musca pendula*, a name given to it in allusion to the habits of the larvæ, which resemble those of *Eristalis* both in structure and locality, as do also those of the perfect insect.

**HELOPHORIDÆ** (Leach). A family of coleopterous insects, belonging to the section *Pentamera* and subsection *Philhydrida* of MacLeay. This family comprises a few genera of minute aquatic beetles which seem to form the connecting link between the true water and land beetles, having clavate antennæ. In this point of view, therefore, the family possess

considerable interest. Unlike the former, the structure of the legs, and the want of ciliæ, or hairs, on the limbs, prevent them from swimming; so that it is rather by walking than swimming that they preserve their aquatic situation. The body is oblong and depressed; the antennæ composed of nine joints, clubbed at the tips; the mandibles are destitute of teeth; and the maxillary palpi very long, a character which they possess in common with the more typical water-beetles (*Hydrophilidæ*); they creep but slowly, and may often be observed in muddy water and at the roots of aquatic plants; sometimes also in fine weather they leave the water and take flight. The genera are *Helophorus*, *Hydrochus*, *Ochthebius*, and *Hydræna*, the first of which is distinguished by the moderate length of the maxillary palpi, which have the last joint thickened and oval, and by the transverse form of the thorax. There are eight English species, the *Silpha aquatica* of Linnæus being the type. It is about a quarter of an inch long, and of a dull brassy brown colour, with the elytra greyish. In *Hydrochus* the thorax is long and the eyes very prominent, whence the typical species is termed *Cicindeloides*, in allusion to its resemblance in these respects to the tiger beetles. In *Hydræna* the maxillary palpi are very long, being nearly half the length of the body.

**HELOPIDÆ** (Stephens; **HELOPII**, Latreille). A very extensive family of coleopterous insects, belonging to the section *Heteromera* and to the subsection *Stenelytra* of Latreille; having the antennæ inserted near the eyes, beneath the lateral margins of the head, nearly filiform, or but slightly thickened at the tips; the joints generally cylindric and slender at the base, the third joint being elongated; the tips of the mandibles have a notch; the maxillary palpi are terminated by a large hatchet-shaped joint; the eyes are oblong, and kidney-shaped; the tarsi generally simple, as well as the claws. These insects, which are generally elegantly marked and variegated in their colours, are for the most part inhabitants of tropical regions, where vegetation abounds, the perfect insects being chiefly found upon the trunks of old and decaying trees; the larvæ, of which very few have been observed, feed also upon the wood of such trees. They are filiform, smooth, and shining, with very short legs, resembling those of the meal-worm (*Tenebrio molitor*). Mr. Stephens introduces the *Cistelides* of Latreille into this family, which have the antennæ exposed at the base, the mandibles entire at the tips, and the tarsal claws toothed. In other respects they are closely allied to the true *Helopidæ*. There are numerous genera established in this family, chiefly founded upon exotic species, of whose habits nothing is known. The English genera are *Helops*, *Eryx*, *Mycetochorus*, *Cistela*, and *Allecula*, which, with the exception of the first, belong to the subdivision of the *Cistelides*. The genus *Helops* is remarkable for having the anterior tarsi of the males dilated. The thorax is transverse, and applied to the base of the elytra. There are four British species, of which the type is the *Helops caraboides*, an insect found abundantly throughout the kingdom at the roots and under the bark of trees and upon the broom. It is of an elongate ovate form, of a pitchy brown colour, and thickly punctured, the antennæ and tarsi being of a dusky red.

**HEMEROBIIDÆ** (**HEMEROBIDÆ**, Leach). A family of neuropterous insects belonging to the section *Planipennes* of Latreille, having the body slender and much shorter than the wings, which are large

and very much reticulated, resembling very fine network; the antennæ slender and filiform; the palpi only four in number, the terminal joint being thicker than the preceding; the first segment of the thorax is very small, and the wings, when shut, are deflexed; the body is soft; the eyes globular, and often splendidly metallic. They fly very slowly. These insects, which in their perfect state seem so delicate and harmless, are produced from grubs which are exceedingly ravenous, very much resembling those of the ant-lion (*Myrmecoleonidæ*) not only in their appearance but also in their ravenous propensities. Like the grubs of the ladybirds, they subsist upon plant-lice, which they seize with their jaws, which are long and curved, and which they suck to death in a very short time. Some of these larvæ moreover invest themselves with the skins of their victims, which gives them an extraordinary appearance. When full grown the larva envelopes itself in a globular cocoon, composed of a very fine tissue of silk, and which in proportion to the size of either the larva or perfect fly is very small. The spinnerets of the larva are placed at the extremity of its body, as in those of the ant-lions. These larvæ are produced from eggs, deposited by the females in patches of ten or a dozen together upon the leaves or stems of various plants, of a white colour, and raised from the leaf upon a long glutinous footstalk of the same colour, finer than a hair. Hence by some authors they have been described as a remarkable species of fungi. From their habits they are thus essentially beneficial from the number of aphides they destroy; and it is a curious circumstance that, like the ladybirds, they should emit a strong and exceedingly disagreeable smell, which remains upon the hand for a considerable length of time. The genera belonging to this family are *Osmylus*, *Nymphæa*, from New Holland, *Drepanopteryx*, *Chrysopa*, and *Hemerobius*.

In *Osmylus*, which comprises the largest British species, (*O. maculatus*, F.) the ocelli are three in number, and the antennæ moniliform. In *Chrysopa* (Leach) the ocelli are wanting, and the joints of the antennæ are cylindric. There are twelve British species, including the type *Hemerobius perla* (Linn.), or the golden-eye, a very elegant species, of a green colour, the wings clear, with green veins. It is a very common species. The *Hemerobii*, as restricted by Dr. Leach, are smaller species, having moniliform joints to the antennæ.

**HEMEROCALLIDÆ**. A natural order of plants comprising eighteen genera, and two hundred and sixty-one species already described. They are mostly fine showy plants, bearing their flowers in umbels or racemes, either white, yellow, red, or blue. They are mostly inhabitants of temperate climates, and are of little utility, with the exception of the aloe, the medical and economical uses of which need hardly be mentioned. Here we find some of the gayest ornaments of the stove, greenhouse, and flower-garden. The alettris, agapanthus, tritoma, &c. belong to this order, and many other equally interesting plants.

**HEMEROCALLIS** (Linnæus) is the day-lily, a common hardy flower-border plant belonging to *Hexandria*, and is so named from the fugacious character of its flowers. It gives a title to the natural order *Hemerocallidæ*.

**HEMIPTERA**. In the Linnæan system of zoology the name of the second order of insects, characterised by having the wing-covers of a consistence

intermediate between the scaly covering of the beetles and the membranous wings of the flies, being semicrustaceous, not meeting together when at rest by a straight suture, but having some portion of the inner margin of one wing-cover folded over the other. In the order thus characterised by the structure of the wings alone, were included the cock-roaches (genus *Blatta*), praying mantes (*G. Mantis*), and locusts and grasshoppers (*G. Gryllus*, Linnæus), having the mouth armed with jaws; and *Fulgora*, *Cicada*, *Notonecta*, *Nepa*, *Cimex*, *Aphis*, *Chermes*, *Coccus*, and *Thrips*, having (with the exception of the last, which has not yet been satisfactorily examined) the mouth suctorial, furnished with a proboscis. Hence De Geer, by a combination of structural characters, and Fabricius, following up his system, derived from the cibarian organs, separated the mandibulated genera from the others, to which the name of *Hemiptera* became restricted, the others acquiring the names of *Ulonata*, Fabr., or *Orthoptera*, Olivier. Latreille, however, adopting a system derived from general instead of isolated characters, separated the *Hemiptera* (which Fabricius termed *Rhyngota*) into two great sections, the first having the wing-covers horizontal and of unequal consistence, the basal portion being coriaceous, and the terminal half membranous, retaining for these the name of *Heteroptera*, and giving that of *Homoptera* to the second section, in which the wing-covers are deflexed and of equal consistence throughout. Moreover, in the first of these divisions the rostrum, or promuscis, as it is termed by Mr. Kirby, arises at the front of the underside of the head, whereas in the second it springs from its posterior portion, near the base of the fore-legs, and sometimes appearing pectoral. Dr. Leach, followed by Mr. Mac Leay and some other English authors, considered these two groups as possessing the rank of distinct orders, the first retaining the name of *Hemiptera*, and the second *Homoptera*. Kirby, also, and Latreille, from their agreement in possessing an articulated proboscis, have however regarded them as belonging only to one order. Mr. Kirby, however, gives the following observations as indicating the chief differences between them:—1st, “the heteropterous section usually sucks the juices of animals, and the homopterous those of plants,” but this is by no means correct: the majority of the former, as well as the latter, are plantisuges; (in the former the hemelytra, besides their different substance) as well as the wings, cross each other; while in the latter the organs of flight are deflexed and do not lap over each other at all. The antennæ, also, of the one are often long, and do not terminate in a bristle; whilst in the other, with few exceptions, they are very short and setigerous. In the *Heteroptera* the body is depressed and flat; in the *Homoptera* convex and thick. In the former the scutellum is one of the principal features of the trunk; in the latter not at all remarkable.

Regarding these points of distinction as of no small importance in the establishment of distinct orders, we find the order *Hemiptera* characterised by the *jointed, sucker-shaped mouth*, the *wings membranous*, covered by *wing-covers*, either *entirely membranous* and deflexed, or *partly coriaceous* and *partly membranous* and horizontal, and the *tarsi never composed of more than three joints*. The mouth is composed of a fleshy articulated canal, terminating in a point inclosing several fine bristles, which are employed as lancets in wounding the substances upon which the insects feed; it is also

furnished externally at the base with a small conical place transversely striated, which represents the upper lip of the other orders. When unemployed this proboscis is laid along the breast, often reaching to or even extending beyond the base of the hind legs; when employed it is protruded forwards.

All the insects belonging to this order undergo a series of moultings, analogous to those of other insects, although less in degree. They are produced from eggs as small active six-legged larvae, having nearly the resemblance of the perfect insects, but entirely destitute of wings or wing-covers. After shedding the skin several times, gaining thereby only an increase of size, they appear as pupæ, but still active, and differing only from the larvæ by having the wings and wing-covers concealed in small cases placed upon the back. Another moulting brings them to the imago state, in which their wings are fully developed. In the apterous, or wingless species, the transformations merely consist in a gradual increase of size at the successive moultings. The pupæ of the *Hemiptera* take as much nourishment as the larvæ.

The majority of these insects are found in their various states upon plants, the juices of which serve for their nourishment; some few however inhabit the water (as the *Nepidæ* and *Notonectidæ*), whilst others reside upon its surface, as in *Gerris*, *Hydrometra*, &c. These appear to prey upon other dead or floating insects; others fly in the air with great agility, although they walk but slowly; and some leap to a great distance, as in the *Cecropidæ*. A few of the species, one only of which is found in our climate, attacks man, namely, the *Cimex lectularius*. The majority are varied in their colours; a few only (as the *Nepa grandis* and large exotic *Cicadæ*) attain a large size; the majority being less than an inch in length.

As above characterised, the order *Hemiptera* is divisible into two sub-orders, or primary classes, the *Heteroptera* and *Homoptera*, the distinctions of which we have already detailed in this article.

The sub-order *Heteroptera* (or the order *Hemiptera* of Leach, Mac Leay, Stephens, &c.) is divisible into two primary divisions, namely, the *Geocorisæ*, or land-bugs, and *Hydrocorisæ*, or water-bugs.

For the characters of the *Geocorisæ*, see our article upon that group, and that upon *Cimex*, in which the various subsections or families are described. For the characters of the *Hydrocorisæ*, see the article upon that group; and for an account of the other sub-order, and its divisions, see the article *HOMOPTERA*, and the various articles referred to from it.

HEMLOCK is the *Conium maculatum* of Linnæus, a common and dangerous British weed. It belongs to the natural order *Umbellifera*, and is nearly related to the genus *Smyrnum*. The death of Socrates has conferred such a celebrity on the hemlock, that more plants have contended for the honour of bearing death to the philosopher than cities for giving birth to Homer. The *Conion* of the ancients was a potent poison administered to those condemned to death by the Areopagus. Theramenes and Phocion, as well as Socrates, were poisoned by it; and although the effects recorded in history are not in correspondence with those we should look for from the common hemlock, it is highly probable that this was the poison employed. That the modern *Conium* is identical with the *Conion* of the Greeks, is rendered probable from its being very common in Peloponnesus, and “most abundant between Athens and Megara,” according to

Sibthorpe. The other plants which have been named as affording the *Concion*: viz., the *Cicuta virosa*, *Eranthe phellandrium*, and *Æthusa cynapium*, are not found in any part of the country. The hemlock, however, is, like others mentioned, a poison to some animals, and innocuous to others. It is said to be fatal to kine, but that horses, goats, and sheep, may feed upon it without danger; and most brute animals can eat it when dry with impunity. Although, whether fresh or dry, it is poisonous to man, yet thrushes will eat the seeds, which are more potent than the leaves.

HEMLOCK SPRUCE FIR is the *Abies Canadensis* of the Hortus Kewensis. An American fir, so called from its branches in tenuity and position resembling the foliage of the common hemlock.

HEMP is the *Cannabis sativa* of Linnaeus. An agricultural annual plant of large stature, and which affords the hemp of commerce. Of hemp there are two principal varieties, esteemed by some writers as distinct species: viz., the European hemp, with opposite leaves; and the Indian, called in the Peninsula, Bang, the leaves of which are alternate. In India, hemp is cultivated as a luxury, and used solely as an excitant. It possesses peculiar intoxicating powers, and produces luxurious dreams and trances. The leaves are sometimes chewed or smoked as tobacco. A stupefying liquor is also prepared; and they enter with opium, betel-nut, sugar, &c., into various narcotic preparations.

In Europe it is largely cultivated, but exclusively for its use in the arts. Its fibres are tough and strong, and peculiarly adapted for weaving into coarse fabrics, such as sail-cloth, and twisting into ropes and cables. Immense quantities are imported into this country for the use of the navy, and large stores kept; for it is not a profitable crop in a well-peopled country where corn is in great demand. The seeds abound in oil, which is relished by the Russians as food; in other countries it is chiefly used by painters, or to burn. The seeds are nutritious, and form a favourite food of cage-birds. But hemp-seed has the very singular property of changing the colour of the plumage of bullfinches and goldfinches from red and yellow to black, if they are fed on it for a long time, or in too large a quantity.

HEMP AGRIMONY is the *Eupatorium cannabinum* of Linnaeus, a British plant, found in damp places. It belongs to the natural order *Compositæ*.

HENBANE is the *Hyoscyamus niger* of Linnaeus, a British biennial herb, found in rubbish heaps, or on uncultivated ground. It belongs to *Solanaceæ*. Henbane is a powerful narcotic, and when taken in any considerable quantity proves quickly poisonous to men and most brute animals; swine are said to be able to eat it with impunity.

HEPATICA (Dilwin), a genus of beautiful little flowering plants belonging to the natural order *Ranunculaceæ*. The *H. triloba*, with its varieties of blue, red, white, and snow-white blossoms, are in every flower-garden, and appear among the earliest gems of the season. It was called *Anemone hepatica* by Linnaeus.

HEPATICÆ, a natural order of the first class in the second grand division *Cellulares*, and comprises small creeping plants, with their leaves arranged in an imbricated manner. They differ from lichens in structure, colour, and fruit; from mosses in the dehiscence of their capsules. Their qualities are mild, if any, and some of them are fragrant.

HEPIALIDÆ (Stephens). A family of nocturnal lepidopterous insects or moths belonging to the subsection of which *Bombyx* is the type, and forming, with the *Bombycidæ* and two other families, the *Lepidoptera pomericiana* of Stephens. The antennæ are very short and necklace-shaped, being simple or but slightly pectinated, although in one of the genera, *Zeuzera*, they are strongly pectinated at the base. The spiral tongue, which forms so conspicuous a feature in the lepidopterous character, is here obsolete, and even the palpi are sometimes represented only by a slight tuft of hairs. The wings are large, narrow, and deflexed, when at rest. The larvæ are large, naked fleshy caterpillars, which feed either on the roots of vegetables or burrow in the soft wood of various trees. They are furnished with sixteen legs, eight of which are abdominal and two anal. The chrysalis is cylindrical, having the abdominal segments strongly armed with small hooks, whereby, immediately previous to assuming the winged state, they are enabled to push themselves forward to the surface of the ground, or to the outside of the tree in which they had the instinct, whilst larvæ, to form a burrow. In their habits, therefore, these insects nearly approach to some of the aberrant *Crepuscularia* or *Ægeridæ*, the larvæ of which feed upon the pith of various trees, and, like them, they are occasionally obnoxious, destroying trees and other useful plants. The family comprises the three English genera *Hepialus*, *Cossus*, and *Zeuzera*.

In the first named genus the antennæ are much shorter than the thorax, and setaceous. The caterpillars live under ground, feeding upon the roots of plants. These moths, of which there are six British species, are termed Swifts by collectors, owing to their rapid flight; the females are generally much larger than the males, and differently coloured, although their markings are similar. One of the species, *Hepialus humuli*, is very common in grassy places during the month of June. The male is of a pure silvery white colour, but the female is of a yellowish buff with darker markings. The male is remarkable for its singular mode of flight, which resembles the motion of a pendulum; and as this is continued for a great length of time over one spot (where the female is probably stationed), and as the insect is often observed in country church-yards, the harmless insect has got the credit of being nothing less than the quiet ghost of some person over whose grave it happens to be seen hovering, and has accordingly thence obtained the name of the ghost moth. This species varies in the expansion of the wings from one inch and three quarters to three inches.

The genus *Cossus* contains the large dingy coloured moth known by the name of the goat moth, from the strong scent emitted by its larva. See GOAT MOTH.

The genus *Zeuzera* contains but a single British species, the wood-leopard moth, *Z. Esculi*, distinguished by having the basal half of the antennæ in the males strongly bipectinated, and in the females wholly, whilst the terminal half is quite naked. The caterpillar feeds upon the wood of the apple, pear, and other trees, but it is a rare species.

HERACLEUM (Linnaeus), a genus of the largest herbs produced in Europe. In England it is called cow-parsnep, or kexes, and is very common in damp meadow ground, making the hay coarse, and of less value. To free a meadow of this plant it should be grazed with sheep till late in the spring. The sheep

eat off the head of the stem, and prevent it rising to seed. It is certainly the *Hercules* of British plants.

**HERBERTIA** (Sweet), a bulbous genus of plants from South America, named in honour of the Hon. and Rev. W. Herbert, an assiduous botanist. It belongs to *Iridææ*, and its species are cultivated with other bulbs in a frame, or warm border, only requiring to be defended from severe frost.

**HERB PARIS** is the *Paris quadrifolia* of Linnæus, a curious British plant belonging to the natural order *Asphodeleæ*, found in damp boggy places under trees.

**HERB ROBERT** is the *Geranium Robertianum* of Linnæus, a common British plant found under every hedge.

**HERIADES** (Spinola), a genus of bees nearly allied to *Chelostoma* (which see), but having the jaws triangular, and the maxillary palpi only two-jointed. They are of small size, and make their nests in old posts and trees. There are two British species.

**HERITIERA** (Hortus Kewensis), East Indian trees, called the "looking-glass plant." They belong to the natural order *Byttneriaceæ*, and thrive in our stoves, in loam and moor earth, and are propagated by cuttings.

**HERMANNIA** (Linnæus), a genus of ornamental shrubs from the Cape of Good Hope. Class and order *Monadelphica Pentandria*, and natural order *Byttneriaceæ*. They are easily managed greenhouse plants, growing in any light soil, and readily struck from cuttings.

**HERMINIUM** (R. Brown), a common British orchis, formerly called *Ophrys monorchis* by Linnæus. Found in damp meadows.

**HERNANDIA** (Linnæus), a genus of large East Indian trees, belonging to *Lawraceæ*. The *H. sonora*, or Jack in a box, is so called from the noise made by the wind whistling through its persistent involucrels. The juice of the leaves is found to be an advantageous and effectual depilatory, as it destroys the hair wherever it is applied, and this without pain.

**HERNIARIA** (Linnæus), or rupture wort, is a genus of creeping and half-shrubby plants, natives of Europe. The flowers are pentandrous, and belong to the natural order *Paronychieæ*. They are highly ornamental when planted on rock-work.

**HERON** (*Ardea*). An interesting order of birds, belonging to the culirostral division of stilt birds or waders, and usually considered as a family, including the various divisions of herons properly so called, and also the bitterns and the night herons. We have already given some notice of the bitterns in the article **BITTERN**, and we have mentioned the general relations of the family in the article **ARDEA**, so that we shall here require to notice only the leading species.

Herons are usually subdivided into three sections—herons properly so called, which have the legs very long; crab-eating herons, which have them much shorter; and egrets, which have the long legs and neck, and slender body of the true herons, but which have often very beautiful produced feathers on the back, by the assistance of which they float very lightly in the air. They are all more or less migrant, and birds of high and powerful flight; but those which have the produced or supplemental feathers, which are understood to be seasonal in most of the species, are generally regarded as being more migratory in their habits than those which have not. Herons, in one or other of their species, are found in most countries of the world. In all places they frequent

the banks of ponds, lakes, and rivers, and some of them are occasionally met with on the shores of the sea. They are stately in their march, and the vast length of their legs, necks, and wings, makes them appear much larger birds than they are in reality, for their bodies are light; and the sportsman who sees a heron on the wing, and succeeds in bringing it down by a shot, is apt to be astonished at the small bird which has come to him, considering the large one that he observed in the sky.

As is the case with all wading birds, they project the feet backwards while they are on the wing, and they generally fly so high, especially on their long journeys, that they are above almost every bird from which they need to apprehend any danger. The falcon, indeed, is the only bird of prey which can rise to the full elevation of a heron; and even from this bird the heron escapes, by doubling the neck back upon the shoulders, as this lessens the weight of the fore part of the body, and consequently allows the hind part to droop till the axis points upward obliquely at the fore part; and it will be readily understood that, when birds fly, the line of course which they attempt to make is the line of the general axis of the body, though the real course made good deviates from this in proportion to the weight of the bird. Herons are very light birds in proportion to their powers of flight, and they get the sky more rapidly than birds of more powerful wing; and therefore, even in the days of falconry, when the heron was favourite sport with the jer or the peregrine, there was no use of flying a falcon at a heron on migratory flight. The times chosen were generally those in which the birds were passing between their feeding-places and those where they nestle, or, at all events, repose. Herons do not, like storks and cranes, rest themselves standing on the ground, at least for any length of time. Their favourite places are on the tops of trees, especially those which have the upper branches lateral, and form a sort of wicker platform. The birds stand upon these, and very generally the whole body is seen above the tops of the trees, in which situation the birds have a noble appearance.

The forward flight of herons is not rapid in proportion to the length of their wings, neither do they move these with so much velocity as many other birds, although they are stroke-fliers rather than gliders on the wing. Birds which glide usually take their gliding-motion after having worked their wings very rapidly for some time; and thus, loosely-made birds, with light bodies and very long wings, never glide, though they continue to keep the sky with very slow action. The peculiar style of the heron's flight is best seen when the bird is nearly on a level with the observer, and retreating, in which situation it will be seen that the body is not the centre of motion, but that there is a point in each wing upon which the body and the tips of the wings appear to swing alternately, the body sinking when the tips are raised, and rising when they are depressed; nor are there any birds which show this motion in so great perfection. Herons are very industrious and successful fishers, but their food is pretty miscellaneous. They eat the spawn of fishes, worms, shelled and naked mollusca, crustaceous animals, frogs, and the smaller mammalia which inhabit near the water. They have but one principal moult in the year, and the sexes do not differ greatly from each other in

appearance; but the young and the old are often so dissimilar, that there are not a few mistakes in many of the descriptions; and this renders it necessary to be cautious how any heron, which is but little known, is erected into a species, or even a variety, until it has been seen both in the young and the adult state. Herons, though most of them frequent obscure and lonely places, have yet a good deal of social feeling about them. Those which, from the nature of their pastures, are forced to migrate, usually migrate in large flocks; and in the breeding-grounds they are generally crowded together, and build their nests even closer than rooks.

THE COMMON HERON (*A. cinerea*). This is the species which is best known in the British islands, in various parts of which, both north and south, it is resident in very considerable numbers, though it was much more abundant in former times, when more of the country was covered with pools and marshes, and the heron was sought for as game. The length of the full-grown bird is nearly three feet and a half, and the stretch of the wings upwards of five feet; the weight is between three and four pounds; greyish-ash is the ground colour of the body, marked with lines of black on the neck, and the parts generally with a black bar on the breast; the occiput, in the mature birds, is furnished with a long pendant black crest, which appears to guide the head when the bird strikes rapidly at its prey, and there are also produced silky feathers on the scapulars; the young want the crest, and also the scapular appendages, and on this account they have sometimes been considered the females, and described as such. The colours are not constant, for individuals are sometimes met with which are nearly white, but which do not, in any other respect, differ from the grey ones.

The common heron, like the raven, is found in almost every part of the world. It (or an analogous bird) has been observed within the arctic circle nearly all round, in all the temperate parts of America, in the East and West Indies, in Egypt, and along the banks of most of the African rivers. Indeed, there is scarcely any humid district on the whole surface of the globe in which this bird has not been found; and it is not unknown in the isles of the Pacific Ocean. Its favourite haunts are always countries covered with tall forests, in the neighbourhood of running or of stagnant waters, as the waters of such places are known to abound most with fish, in consequence of the rich supply of insect and other food upon which fishes subsist. It is capable of subsisting a very considerable time without feeding, though it often exposes itself to the severest weather while waiting for its prey. It is a most ravenous feeder when prey is to be had in plenty, and its digestive powers are equal. No bird is so formidable to the fishes of ponds, lakes, and small rivers, as the heron. In fresh water it will strike at, and wound, with its powerful bill, fishes which it is unable to lift out of the water; but it prefers smaller ones, which it can swallow readily either standing or on the wing. When it has advanced as far into the water as it can, without wetting its feathers, it awaits patiently the approach of its victims, into which it darts its bill with undeviating aim whenever they come in contact. Withougbby tells us that he saw a heron swallow no less than seventeen carp, which he estimated the bird could digest in six or seven hours, and then go to fish again.

It is vulgarly reported that the heron has a good deal of trouble when fishing for eels, because those slippery animals will not remain in the stomach, so that the bird may have to swallow the same eel a dozen times over. This is of course incorrect, for the stomach of a bird of far less digestive powers than a heron is a "bourne from which no living traveller can ever return," or escape by any self-exertion; and, besides this, we believe that, when the eels are of considerable size, so that they twist and wriggle about the bill of the heron, the bird always makes for the land, and finishes them by breaking the skull either with a dart of the bill or a stroke of the foot. That herons capture a vast number of eels is certain, and they carry them as favourite food for their young; but if an eel is swallowed as food for the swallower it appears no more. Though the heron usually takes his prey by wading into the water, he frequently also catches it on the wing; but this is only in shallow waters, into which he darts with more certainty than into the deeps, instantly pinning the fish to the bottom, and thus seizing it more securely. After having been seen, in this manner, with his long neck under water for a minute or so, he will rise on the wing with a trout or eel in his bill, and, after swallowing it entire either on the shore or in the air, will immediately return again to fish. Herons are frequently observed to feed by moonlight, when the fish come into the shallow waters. In fact, they are semi-nocturnal in their habits, and they prey on sea-fish as well as on those in the fresh waters. The different parts of their structure are admirably adapted to their mode of life, for they have long legs suitable for wading, a long neck to reach their prey, and a capacious gullet to swallow it. Their toes are long, and armed with long hooked talons, one of which is serrated on the edge, the better to retain the slippery spoil. The bill is likewise long and sharp, having serratures towards the point, which stand backwards, and act like the barbs of a fish-hook. Its broad and concave wings are of signal service in enabling it to convey its load of nourishment to the nest, and to transport its comparatively small and meagre body to distant regions. When we add to these circumstances the acute vision and patient vigilance of this bird, we shall see no reason for indulging in the gloomy strictures of Buffon, who would represent it as an instance of neglect and cruelty on the part of nature, as if the supremely wise and good Creator of all could ever destine animals to a life of wretchedness and misery. The heron has a very melancholy air, is exceedingly shy, and impatient of confinement. The young, to a certain extent, are capable of being tamed; but if the old ones are captured, they obstinately refuse all sustenance, and pine to death. In this state they have sometimes survived for a length of time. They fly very high in the air, especially before rain, frequently soaring beyond the reach of human vision. They are frequently inactive in the daytime, and indulge in repose, but seldom sleep during night, at which time they generally feed, and are very clamorous and noisy. Their cry is shrill and grating, shorter and more plaintive than that of the goose, but repeated and prolonged into a more piercing and discordant note when the bird feels uneasy or pained. They are often disquieted, from being suspicious, and naturally timid; and the appearance of a man, though at a distance, greatly alarms them; nor is it easy to

approach near them without raising them on the wing. They are particularly afraid of the more powerful hawks and of the swamp eagles, especially when they are fishing, and spy a bird of this kind above them; but, when driven to extremities, they fight with considerable resolution either on the ground or in the air; and, indeed, they can strike desperately with the bill, though winged or otherwise crippled. A place where herons breed, for the nests are scarcely ever single, is called a heronry. The nests are broad and shallow, formed of sticks, and lined with soft vegetable matters, or with wool, if the birds can procure it. They are very constant to their breeding-places; and Dr. Heysham mentions an instance, in which a dislodged colony of herons took possession of part of a rookery, but not until after a desperate battle, in which many on both sides were killed. The eggs of the heron seldom exceed four, but they are sometimes as many as six. They are of a greenish-blue colour, and about the size of ducks' eggs. The female sits closely during the incubation, and is fed by the male; and, after the young are hatched, both birds join in the labour of feeding them, which, from their voracity and vigorous digestion, is no easy task.

THE GREAT HERON (*A. herodias*). This is an American species, resembling the common heron of Europe both in shape and in colour; but it is considerably larger in size, and almost double the weight. Its length from the point of the bill to the tail is four feet four; and the legs extend a foot beyond the tail. The extent of the wings is fully six feet; and the weight not less than seven pounds, while that of the common heron is generally less than four. It is highly probable, however, that when the common heron is mentioned as an inhabitant of North America, this is the bird alluded to; and though the size is larger, the bill longer, and the feet differently coloured, it is probable that the origin of the two may have been the same.

Abounding as it does in woods and waters, above all countries of the same extent which are met with on the surface of the earth, America is the very home of the herons. The species are very numerous, and the birds themselves abundant; and though the woods of America are remarkable for the multitudes of their birds, there is perhaps no race which are so characteristic as the herons. It would far exceed our limits to give any thing like a detailed account of the different species or of the peculiarities of the country; but we shall quote a passage from Wilson, in which the singular dwellings of the birds are portrayed with more graphic effect than has been done or could be done by any other writer, even though, like Wilson, a personal visitant. After mentioning that they are found in greater numbers on the Atlantic coast than in the central valleys, and pointing out some localities which are favourite ones with them, Wilson thus proceeds to describe their building-places. "These are generally in the gloomy solitudes of the tallest cedar swamps, where, if unmolested, they continue annually to breed for many years. These swamps are from half a mile to a mile in breadth, and sometimes five or six in length, and appear as if they occupied the former channel of some choked up river, stream, lake, or arm of the sea. The appearance they present to a stranger is singular. A front of tall and perfectly straight trunks, rising to the height of fifty or sixty feet without a limb, and crowded in every direction, their tops so closely woven together as to

shut out the day, spreading the gloom of a perpetual twilight below. On a nearer approach, they are found to rise out of the water, which, from the impregnation of the fallen leaves and roots of the cedars, is of the colour of brandy. Amidst this bottom of congregated springs, the ruins of the former forest lie piled in every state of confusion. The roots, prostrate logs, and, in many places, the waters, are covered with green mantling moss; while an undergrowth of laurel, fifteen or twenty feet high, intersects every opening so completely, as to render a passage through laborious and harassing beyond description; at every step, you either sink to the knees, clamber over fallen timber, squeeze yourself through between the stubborn laurels, or plunge to the middle in ponds made by the uprooting of large trees, and which the green moss concealed from observation. In calm weather, the silence of death reigns in these dreary regions; a few interrupted rays of light shoot across the gloom; and unless for the occasional hollow screams of the herons, and the melancholy chirping of one or two species of small birds, all is silence, solitude, and desolation. When a breeze rises, at first it sighs mournfully through the tops; but, as the gale increases, the tall mast-like cedars wave like fishing-poles, and, rubbing against each other, produce a variety of singular noises, that, with the help of a little imagination, resemble shrieks, groans, growling bears, wolves, and such like comfortable music. On the tops of the tallest of these cedars the herons construct their nests, ten or fifteen pair sometimes occupying a particular part of the swamp. The nests are large, formed of sticks, and lined with smaller twigs; each occupies the top of a single tree. The eggs are generally four in number, of an oblong pointed form, larger than those of a hen, and of a light greenish blue, without any spots. The young are produced about the middle of May, and remain on the trees until they are full as heavy as the old ones, being extremely fat before they are able to fly. They breed but once in the season. If disturbed in their breeding-place, the old birds fly occasionally over the spot, sometimes hooting like a goose, sometimes uttering a coarse hollow grunting noise, like that of a hog, but much louder. The great heron is said to be fat at the full moon, and lean at its decrease; this might be accounted for by the fact of their fishing regularly by moonlight through the greater part of the night, as well as during the day; but the observation is not universal, for at such times I have found some lean as well as others fat. The young birds are said to be excellent for the table, and even the old birds, when in good order, and properly cooked, are esteemed by many. The principal food of the great heron is fish, for which he watches with the most unwearied patience, and seizes them with surprising dexterity. At the edge of the river, pond, or sea-shore, he stands, fixed and motionless, sometimes for hours together. But his stroke is as quick as thought and as sure as fate, to the first luckless fish that approaches within his reach; these he sometimes beats to death, and always swallows head foremost, such being their uniform position in the stomach. He is also an excellent mouser, and is of great service to our meadows, in destroying the short-tailed or meadow mouse, so injurious to the banks. He also feeds eagerly upon grasshoppers, various winged insects, particularly dragon-flies, which he is very expert at striking; and also eats the seeds of that

species of nymphae called splatterdashes, so abundant along our fresh water ponds and rivers. The heron has great powers of wing, flying sometimes very high, and to a great distance; his neck doubled, his head drawn in, and his long legs stretched out behind him, like a tail, and probably serving the same rudder-like office. When he leaves the sea-coast, and traces, on wing, the courses of the creeks and rivers inland, he is said to prognosticate rain; when downwards, dry weather. He is most jealously watchful of man, so that those who wish to succeed in shooting the heron must approach him entirely unseen and by stratagem." "In our vast fens, meadows, and sea marshes, this stately bird roams at pleasure, feasting on the never-failing magazines of frogs, fish, seeds, and insects, with which they abound, and of which he probably considers himself as the sole lord and proprietor. I have several times seen the white-headed eagle attack and seize the great heron; but whether for sport, or to make him disgorge his fish, I am uncertain."

This is the characteristic heron of the Atlantic shores of the United States, not ranging so far to the north as the St. Lawrence, or very far into the interior. There are many smaller herons in America which are more discursive and migratory on the meridian; but the journeys of this one are chiefly from the sea to the base of the Alleghany mountains and back again.

**GREAT WHITE HERON (*A. alba*).** This species, though inferior in size to the former, appears very conspicuous from its colour. Some have alleged that it occurs, though exceedingly seldom, as a visitant in Britain; but the fact is not clearly established, neither is it well ascertained whence it would come in the event of its visiting our shores. It is found both in the eastern and in the western continent, or, at all events, there is but little difference between a bird which is known by the same appellation in each; and as the manners of the great grey heron of America are very similar to those of the common grey heron of Europe, so the manners of those birds which are referred to this species very much resemble each other.

The grey herons are resident birds rather than migrants, or, at all events, their excursions are between the shores and the inland in the same localities. The white herons, on the other hand, are emigrants, inhabiting climates farther to the south, where the seasonal alternations of wet and drought are much more marked. In the eastern continent they appear to belong chiefly to the central migration, or that which takes the line of the Caspian and the Black sea; while in America their range is between the valley of the Mississippi and the humid districts of the northern parts of South America. They are much more numerous in America than in the eastern continent, and distribute themselves as well along the coast as in the central valley. They arrive in the more southerly states early in the spring, proceed northward, and build in the cedar swamps nearly in the same manner as the great herons, which they also resemble in their general manners. The following are the characters of these birds: length from the tip of the bill to the tail three feet and a half; and extent of the wings about five feet. The feathers of the back extend, however, as much as seven or eight inches beyond the point of the tail. These feathers arise from the lower parts of the scapulars and sides of the back. The shafts are long

and tapering, and the webs consist of delicate filaments, very soft, and detached from each other. This plumage is peculiarly graceful and waving; and it hangs in an elegant curve over the hinder part of the body, completely concealing the tail. The plumes of this heron have at times been much prized in various parts of Europe, as graceful ornaments of the head; and the American Indians employ them for the same purpose. In the lower valley of the Mississippi they are obtained in such numbers that the Indians hawk them about in the streets of New Holland. These produced feathers have a delicate yellowish tinge, but all the rest of the plumage is of snowy whiteness. The bill is about half a foot long, of a bright orange colour, and black at the tip; the irides are pale orange, and the pupil very small; the legs are very long and stout, bare for four inches above the tarsal joint, and altogether of a black colour; the toes are long, the middle and hind one stretching nearly six inches from tip to tip; the middle claw is toothed on its inner edge, and the middle and exterior toes are united by membrane for about half an inch at the base. This structure of the foot is equally well adapted for walking on aquatic plants and on soft and muddy ground; and the length and strength of the legs, together with the extent to which they are naked of feathers, enable the bird to wade deeply without wetting its plumage. In the mature state, the male and female resemble each other very closely; and both have their produced feathers equally long. The young birds are different; and they do not acquire their perfect plumage till they are three years old, which indeed is the case with all the herons. The young birds have the common clothing feathers quite like the old ones; but they have not the produced feathers on the back: this circumstance has caused the old birds and the young to be sometimes described as different species, and at other times the ones without the produced feathers have been considered as the females; but this is not correct, for both sexes want these feathers while young, and both have them after arriving at maturity.

This species of heron is very widely distributed, being found as far to the south as India, where it is very abundant in the rainy season, though it disappears during the drought. The beauty of its plumage, and the high estimation in which the produced feathers have been held, have made it a bird of no little celebrity. It is the *Egret*, or great egret of common description, though we believe the proper meaning of that word is the ornament made of the feathers, and not those feathers as they exist on the bird.

**LITTLE WHITE HERON (*A. garzetta*).** This species is also very generally distributed, and is still more discursive than the larger one. It occurs most plentifully in latitudes and localities similar to those frequented by the other; but it ranges farther to the north, and also more extensively in longitude. It is the little egret of the East, and the snowy heron of America. The American one is indeed a little larger in size than the eastern one, and there are some slight differences in the colour of the naked skin; but those differences do not appear to be greater than they are in the grey heron of the two continents, and certainly they are not greater than might be expected to arise from difference of climate.

The grand difference between the American continent and the Eastern, is worthy of being attended to in deciding upon what is or is not the same species

of animal, as occurring in the two. In the central parts of the eastern continent, drought is the prevailing character of the climate; and in America, on the other hand, humidity predominates just as much. Now, in order to ascertain whether we ought to expect any animal to thrive better, that is, to attain a larger size and a more complete development, in the one continent or in the other, we must attend to the nature of the animal, so as to ascertain whether a dry climate or a humid one is the more congenial to it. If the former, we may presume that if the animal is native in America as well as in the eastern continent, it will be smaller and less perfectly developed in America; or if it is imported from the East to America, it will degenerate. We have a remarkable instance, in the case of animals of the same family, in the genus *Felis*, as existing in the two continents. There is no question that the whole of that genus are animals which prefer drought, and many of them cannot bear a wet climate. Hence we do not find in any part of America animals of such power and daring as the lions and tigers of the East.

But on the other hand, if the nature of the animal adapts it more to a humid climate, we may expect to find the same species more developed as native of America than as native of the East; or if imported from the East into America, we may expect it to improve. Here again we may take an illustration from the mammalia of the two continents. Bears, from their protecting coat of fat, and their strong and close hair, which completely thatches them against the weather, are remarkably well fitted for moist climates; and accordingly we meet with no land bears in the eastern continent at all equal in size, in boldness, or in strength, to those of America.

Now, if we apply this theory, which is very obviously true, to the case of herons, which are found only in marshy places, we can easily see that these birds possess such natural advantages in the American continent, as must lead us at once to conclude that the same species must attain a larger size and a more perfect development there. Food for herons, and also trees adapted for their nesting-places, are vastly more abundant in America than in the eastern continent, and therefore the birds have more enjoyment and less labour.

This is a point in the physiological geography of animals, which, so far as we are aware, has not been alluded to by any writer on the subject; but it is one of very great importance, not in helping us to explain some climatal modifications of animals, which otherwise would be a little perplexing, but as a warning against some very ridiculous prejudices which have been taken up by the romancers in natural history; and which, in consequence of the imposing style in which they are stated, have gained no small currency with the public. Taking up an exceedingly partial view of the case, namely, that of one or two animals, and not considering whether the climate of the east or that of the west suited best with the nature of those animals, these romancers of natural history have come at once to this sweeping conclusion, that "there is a tendency in nature to belittle all her productions on the west side of the Atlantic." It was somewhat natural that a sentence of condemnation so sweeping as this should occasion some wrath on the part of the American naturalists, though it does not appear that they got more into the philosophy of the case than their brethren of the east; and indeed, to

speaking about any tendency which nature has, either to deteriorate or to improve her productions in one country more than another, is to utter words which have no meaning. That the whole system of nature, in all its parts, is equally perfect, is the fundamental truth; and though we cannot in all cases draw a clear line of distinction between that which determines a natural character, and that which possesses the character so determined, yet we may state it as perfectly general, that, according as any place is, so will be its productions; and the very beauty of the earth, and that which gives it its greatest value to man, as making the different nations in so far dependent upon each other, and thus pointing out to them the bonds of general peace and reciprocal assistance, is the diversity of climate and surface, and consequently of productions, in the several countries and their several districts. But, important as this point is, and necessary as it is that it should be strongly inculcated, as extending much farther than mere matters of natural history, we must leave it, and return to the little white heron.

Little Egret.

The length of this species is about two feet, and the extent of the wings between three and four; the weight rarely exceeds one pound. All the plumage is of the most brilliant white; the bird is furnished with a pendent crest, formed of a few long, straight, and waving feathers. There is a large tuft of similar feathers on the lower part of the neck, which are very straight and beautiful in their lustre. From the top of the back there proceed three ranges of feathers, about six or eight inches in length, with slender shafts, and the webs thin and light, and in detached filaments of a beautiful silky texture. The bill is black; the naked skin round the eyes greenish; the irides brilliant yellow; the upper parts of the tarsi, and the naked portion above the joint, greenish black; and the lower parts of the tarsi and the toes greenish yellow. The young want the produced feathers on the neck and the back. In the first year they are of a dull white, with the bill, the irides, and all the naked skin black. They build in marshy places, and the hatch consists of four or five white eggs.

Perhaps these are the most interesting birds of the

whole heron family. They are particularly handsome; and they are social and gentle in their manners, associating readily with other birds, and capable of being tamed without any great difficulty. Their plumes were once in high demand for adorning the helmets of the mailed warriors of the middle ages; and they are still used for decorating the head-dresses of ladies, and the turbans of persons of rank in the East.

In England these birds are now exceedingly rare, though one was found in South Devon in the early part of the present century. It was a female, supposed to be a young bird of the first year, but all pure white, with the exception of the crown of the head and the upper part of the neck in front, which were buff-coloured. Some idea may be formed of their abundance in times gone by, from the fact, that a thousand of them were served up at the grand feast given by Archbishop Neville, though at present it would puzzle all the bishops of England to collect a dozen in the whole country during a century. The following quotation from Wilson will enable those who take an interest in these very handsome birds, to compare the American one with the eastern, to which latter our observations have been chiefly applicable. "On the 19th of May," says he, "I visited an extensive breeding-place of the snowy heron, among the red cedars of Summer's Beach, on the coast of Cape May. The situation was very sequestered, bounded on the land side by a fresh water marsh or pond, and sheltered from the Atlantic by ranges of sand-hills. The cedars, though not high, were so closely crowded together as to render it difficult to penetrate through among them. Some trees contained three, others four nests, built wholly of sticks. Each had in it three eggs, of a pale greenish-blue colour, and measuring an inch and three quarters in length, by an inch and a quarter in thickness. Forty or fifty of these eggs were cooked, and found to be well-tasted; the white was of a bluish tint, and almost transparent, though boiled for a considerable time; the yolk very small in quantity. The birds rose in vast numbers, but without clamour, alighting on the tops of the trees around, and watching the result in silent anxiety. Among them were numbers of the night heron, and two or three purple-headed herons. Great quantities of egg-shells lay scattered under the trees, occasioned by the depredations of the crows, who were continually hovering about the place. On one of the nests I found the dead body of the bird itself, half-devoured by the hawks, crows, or gulls. She had probably perished in defence of her eggs. The snowy heron is seen at all times during summer among the salt marshes, watching and searching for food, or passing, sometimes in flocks, from one part of the bay to the other. They often make excursions up the rivers and inlets, but return regularly in the evening to the red cedars on the beach to roost. I found these birds on the Mississippi early in June, as far up as Fort Adams, roaming about among the creeks and inundated woods. The length of this species is two feet one inch: extent, three feet two inches! the bill is four inches and a quarter long, and grooved; the space from the nostril to the eye orange yellow, the rest of the bill black; irides vivid orange; the whole plumage is of a snowy whiteness; the head is largely crested with loose unwebbed feathers, nearly four inches in length; another tuft of the same nearly covers the breast; but the most distinguished ornament of this bird is a

bunch of long silky plumes, proceeding from the shoulders, covering the whole back, and extending beyond the tail; the shafts of these are six or seven inches long, extremely elastic, tapering to the extremities, and thinly set with long, slender, bending threads or fibres, easily agitated by the slightest motion of the air; these shafts curl upwards at the ends. When the bird is irritated, and erects these airy plumes, they have a very elegant appearance. The legs and naked part of the thighs are black; the feet, bright yellow; claws black, the middle one pectinated."

**CRESTED PURPLE HERON (*A. purpurea*).** This species appears to be wholly confined to the eastern continent, and to belong to the south-eastern migration. It is very common in the marshy places of Eastern Europe and Western Asia, in the north of Africa, and in the islands of the Mediterranean. It is not, however, mentioned as occurring even as a migrant in the peninsular part of India. In the west of Europe it is rare, and in the British islands it appears only as a very rare straggler. It is a marsh bird, building in tall reeds and other aquatic plants, and rarely perching on trees. The hatch consists of three eggs of a greenish ash colour, and without any gloss or lustre.

Crested Heron.

This is a very beautiful bird, and one of considerable size, the length, when full grown, being about three feet, and the stretch of the wings not less than four. The mature birds have a crest of long and slender feathers on the hind head, which are of a greenish black colour. At the lower part of the neck there are similar feathers of whitish purple; and the feathers on the scapulars and upper part of the back are also slender and produced, but they are bright purple. The top of the head is black, with bright green reflections; the throat white; the sides of the neck bright russet; there are three longitudinal stripes of black on the neck, one on each side from the eye downwards, and the third behind, but not extending to the lower part of the neck; the lower neck is mottled with longitudinal spots of russet, purple, and black; the back, the wings, and the tail are reddish ash, with purple reflections; the thighs

and abdomen russet, the flanks bright purple, and the breast the same; the bill and naked skin round the eyes are bright yellow; the irides orange yellow; the under parts of the toes, the rear of the tarsi, and the naked skin above the tarsal joints, yellow; and the scales on the fore parts of the tarsi and upper parts of the toes greenish brown.

The young have no crest on the hind head, although its place is indicated by the feathers being a little more produced, and they also want the long feathers on the neck and the scapulars; they have the forehead black, the nape and cheeks bright red, the throat white, the hind part of the lower neck yellowish white, with lines of black; the back, scapulars, wings, and tail, are blackish ash, bordered with bright russet, and the thighs and belly white; a considerable part of the upper mandible is blackish, but all the under one, and the naked skin round the eyes, bright yellow. In this state they have been described as a separate species, under the name of the African Heron. In its nesting-places this bird resembles the bitterns; but in its food, and manner of obtaining it, it is a true heron, differing little in these respects from the common grey heron.

THE SQUACCO HERON (*A. rallioides*). This species has the tarsi much shorter than the typical herons, and in this respect approaches to the bitterns, but, in many traits of its character, it has more resemblance to the herons, and, like them, it is said to nestle in trees. It is a very beautiful bird, and, though neither so striking or so showy in its plumage as the white herons, which have the produced feathers, it makes a very remarkable contrast with them. The feathers on the top of the head are yellow, margined with black; the crest, which consists of long and very narrow pendent feathers, has each feather white in the centre and black on the margin; the throat is white; the neck, the scapulars, and the upper part of the back, bright russet; and the produced feathers, which are very loose and flocculent in their webs, are rich maroon. All the rest of the plumage is pure white. The basal part of the bill is azure, and the tip black; the naked skin round the eyes greenish grey; the irides yellow; and the feet yellow, with a tinge of green; the garter, or naked space above the tarsal joint, is very short; the length is about seventeen inches.

The young, till the third year, want the produced feathers; they have the head, the neck, and the coverts of the wings, reddish brown, marked with dark oblong spots of the same; the throat, the rump, and the tail, are pure white; the quills ash-colour, with the inner webs white; the middle of the back and the scapulars pale brown; the upper mandible greenish brown, and the lower greenish yellow; the naked skin round the eyes green; the irides bright yellow; and the feet greenish ash. The nests are in trees, but the number and appearance of the eggs are not very well known.

From the shortness of the tarsi, and the unfeathered part of the tibiae above the joint, it may be inferred that these birds do not wade so far into the waters or fish so habitually as the more typical herons. They do catch fish, but their food consists fully as much of insects, shelled mollusca, and the smaller crustacea, and, on the last account, they have been styled "crab-eaters."

This species is very abundant in the countries around the Mediterranean, and in the marshy parts of Eastern Europe and Western Asia. It also comes

very frequently into Germany, Switzerland, and France, though only as a migrant. It is also more frequently seen in England than any of the other herons which belong to the south-eastern migration, but still it does not come so habitually, or in such numbers, as to rank as a regular visitant.

In many parts of the warmer countries there are short-legged herons which bear a considerable resemblance to this one, and which are also styled crab-eating herons. So little is known respecting them, however, especially with regard to their nesting and their plumage in the young and adult states; and in those parts of their history which are known, they bear so close a resemblance to this one, that nothing further could be added that would be of much interest to the general reader. There is, however, one other species, which is still smaller and more discursive than any of those already mentioned, and therefore it may be worth mentioning.

LITTLE HERON (*A. minuta*). This species is sometimes called the Danube heron, from its being frequently seen in the valley of that river, though we believe this name has been applied chiefly to the young, which, as in the rest of the genus, differs greatly from the mature bird in its plumage. The top of the head, the nape, the back, the secondary quills, and the tail, are of a rich black, with brilliant reflections of green; the sides of the head, the neck, the wing-coverts, and all the under parts of the body, are reddish yellow, and the principal quills are blackish ash; the bill is brown at the point, and yellow in the rest of its length; the naked skin round the eyes and the irides are yellow, and the feet yellowish green. The length of the bird is about fourteen inches, and the size nearly the same as that of a thrush.

The young of the first year have the bill brown and the feet green; the top of the head brown, and the back of the neck whitish, with numerous longitudinal brown streaks; the sides of the head, the nape, the breast, the back, and the wing-coverts, reddish brown, more or less dark, and mottled over with numerous longitudinal brown streaks. It is in this plumage that the bird is the rayed bittern of Latham; and some other British describers. On the second moult the longitudinal spots begin to disappear, the plumes on the neck are bordered with russet, and the feathers of the wings and tail begin to turn black.

This species is still less of a wader than the one last mentioned. It has no part of the leg bare of feathers above the tarsal joint, and the membrane which unites the middle toe and the external one at their basis is very short. Still it frequents the marshy grounds and margins of the waters, feeding upon young fry and very small fishes in the shallows, and also on the spawn and tadpoles of frogs, and on worms. It is a marsh-breeder, making its nest in bushes and tufts, and laying five or six white eggs.

It is wholly confined to the eastern continent, but there it has a considerable range, being met with as far to the north as Siberia, and as far to the south as Arabia. In the south and east of Europe it is very common, and it is by no means rare in Holland. In France it is not so abundant; and in England, and, as it is said, in Germany, it is only a bird of passage. Considering its size, it is a bird of long and powerful flight, and some of the specimens that have straggled to this country have been met with in the Orkney islands. Some describers mention, that, during the breeding season, the male utters a cry resembling the

barking of a large dog when at a distance. In those places where it comes as a straggler it is not exclusively found close by the waters, as is the case with those herons which are more exclusively fishers; it ranges the moist meadows and damp corn-fields, but the former only where the grass is sufficiently tall for affording it concealment.

**LOUISIANA HERON** (*A. Ludoviciana*). This is, as its trivial name imports, an American species, but to the northward of Carolina it is seldom found on the Atlantic shores, nor does it advance far up the valley of the Mississippi in its northern migrations. It is not known as a resident bird in any part of North America, but its home is said to be in the marshy districts of the north parts of South America. Its length, from the tip of the bill to the end of the tail, is twenty-three inches; the long hair-like plumage of the rump, and lower part of the back, extends several inches farther; the bill is of considerable length, measuring at least five inches, of a yellowish green colour at the base, black towards the point, and very sharp; the irides are yellow; chin and throat white, dotted with rust-colour, intermingled with blue; the rest of the neck is of a light vinous purple, intermixed on the lower part next the breast with dark slate-coloured plumage; all the feathers of the neck are long, narrow, and pointed; head crested, consisting of, first, a number of long, narrow, purple feathers, and under them seven or eight pendent ones, of a pure white, and twice the length of the former; upper part of the back and wings light slate-colour; lower part of the back and rump white, but concealed by a mass of long unwebbed hair-like plumage, that bends over the tail and tips of the wings, extending three or four inches beyond them; these plumes, at the base, are of a dirty purplish brown, and lighten towards the extremities to a pale cream-colour; the tail is even at the tip, somewhat longer than the wings, and of a beautiful fine slate-colour; the legs and thighs, which are naked, are greenish-yellow, the middle claw pectinated; the whole of the under parts are pure white; the plumage of the male and female is alike, both being crested.

The tropical parts of America, New Holland, and the Eastern Islands, possess various species of herons, of which, generally speaking, the manners are but little known. Some of these appear to belong to the family of the true herons, and others more resemble the bitterns in some particulars. Of these, the *Agami heron* of the north parts of South America is a very splendid bird. The upper parts are bluish ash; the head and crest, which consists of very long feathers, are black; the nape and upper part of the neck bluish, the under parts and under tail-coverts russet brown, the bill black; the feet yellow, the rump furnished with long floating feathers of a dull blue colour; the belly spotted with white, the length about two feet and a half. It would, however, be impossible to enter into anything like a popular account of those tropical herons, both on account of the number of the species and from our ignorance of their manners. But there are still one or two deserving of notice, which migrate into the more temperate latitudes during the summer.

**THE BLUE HERON** (*A. cærulea*). There are blue herons in different parts of the world; and some are met with as distant as New Zealand; but the one with which we are best acquainted is an American species, resident in the tropical parts during the win-

ter, but migrating into the warmer and more southerly portion of the United States during the summer. It belongs to that division of the herons which have a slight resemblance to the bitterns. It is much less powerfully winged than some of the others. Its length nearly two feet, and the stretch of its wings about three. The bill black, with a bright purple streak extending from the nostril to the eyes; irides grey, with a narrow ring of a silvery colour round the pupil. The head and greater part of the neck deep purple brown; the crest-feathers narrow and pointed, and about six inches in length. The lower neck and the body generally of a deep slate blue with reflections of lighter colour. The back furnished with long, flat, and narrow feathers, some of them ten inches long, and reaching four inches beyond the tail; and there is a tuft of similar feathers on the fore neck or upper part of the breast. The legs are blackish green, and the claw on the middle toe is toothed like a comb on its inner edge. The breast, sides of the rump, and some other of the under parts, are furnished with a close cottony down below the proper feathers. The sexes are exactly alike in their general appearance; but the young birds are different. Though differing much in colour, this species appears to hold nearly the same place on the western continent as the squacco herons do on the eastern. When they retire at the approach of winter, they pass into Mexico, and all the intermediate parts; and in their southern rambles they probably reach the plains of Paraguay during the rainy season. In the extreme north of the United States they are rare; and in the middle States they are partial to the brackish water and the salt springs. They are tree breeders, and nestle in the tops of cedars, in the swamps, along with the night herons. The nests are constructed of small sticks, and the eggs average about four and are of a pale blue colour.

**YELLOW-NECKED HERON** (*A. violacea*). This is another of the American migrants, coming northward in the summer, and returning southward in the winter. It is rather a more southerly inhabitant than the one last mentioned, and is seldom met with farther north than the Carolinas, and even there it is not numerous, or much seen in proportion to its numbers, being a very shy and retiring bird. When we speak of the limits of a bird's migration in such a country as America, we must be understood as speaking of those places only to which the bird comes every year, and comes in considerable numbers; for among the rarer migrants of Britain, we occasionally find a pair straggling over to breed, while there is no regular summer residence of the birds within several hundred miles; and in North America, where there is no sea to interrupt migration, or cause a marked change of country upon the one shore and the other, the range of migration not only naturally but necessarily varies with the range of the seasons. If the season is backward and cold, the range will thereby be checked; and if, on the other hand, it is forward and warm, the range may be extended, in the case of a few of the birds at least, to a very considerable distance beyond the average. Hence this species of heron, though unquestionably rather a southern one, is occasionally found breeding in Virginia, and perhaps even farther to the north; and in those northerly parts the young birds are eagerly sought after, being highly esteemed as food. This bird is common in many parts of the West India islands, and great numbers are said to

breed in the Bahamas, and to feed on the fry of fishes and mollusca and small crustacea, which, in consequence of the currents of the sea there, are remarkably plentiful in the eddies of shallow water, in the creeks, and on the banks. It appears indeed that this species is more partial to the sea-coast, and feeds more on crustacea, especially on the smaller kinds of crabs, than any other heron of the western continent.

Its length, from the tip of the bill to the end of the tail-feathers, is about one foot ten inches, but the flowing plumes extend about four inches farther; the stretch of the wings is about two feet ten inches; the bill is about four inches in length, of a black colour, very stout, and having the upper mandible with grooves, like the bill of the night heron; the naked skin from the gape to the eyes is pale green, the irides flame colour, and the legs and feet yellow, with the middle claw toothed; the upper part of the head is white, and the crest is pure white and terminates in two narrow tapering feathers more than half a foot in length, and under these feathers there are a few mottlings of black. All the rest of the neck and the lower parts of the body are bright ash-colour, a little paler at the junction of the neck; the upper parts are dark ash, each feather with a white border and a black line down the centre; the quills of the wings slate blue with white edges, and the coverts the same colour but with pale buff borders. From the scapulars arise the produced feathers, which have long and tapering stems, and very loose and flocculent webs; they are ash-coloured with a broad streak of black down the middle; the sides of the head and upper part of the neck are black marked with a white spot on each side.

THE NIGHT HERON (*A. nycticorax*). This species, which is in some of its characters intermediate between the herons and the bitterns, but which appears to resemble the herons more in its manners, has been arranged and described as a separate genus; but though extreme scientific nicety may justify those very minute generic distinctions, it does not appear that they can contribute very much to any useful popular purpose; and therefore, to prevent repetition, and also to enable the reader to judge better of the distinctions between it and the typical herons, we introduce it here.

The night heron, or at all events a night heron, is found both on the eastern continent and on the western; and their manners, which is really the important part of the history of any bird, appear to be so much alike that they may be considered as the same species; and not more different from each other, even from the effects of climate, than some of those other species to which we have already alluded. They get the name *Nycticorax*, or night croaker, from the loud and disagreeable noise which they make during the night. In America they are vulgarly called *Qua-birds*, because the noise which they make has some slight resemblance to the sound of that syllable when pronounced in a manner as harsh and guttural as possible.

This bird, of which the new scientific name is *Nycticorax gardeni*, is very common in all the extensive swamps of both continents. In Britain they do not breed, and therefore we have no opportunity of observing the places of the nests, or the habits of the birds in their breeding quarters. Temminck says that it nestles on the ground in bushes, and very

rarely in tufts of rushes, and lays three or four eggs of a dull green. But Temminck is not always to be trusted with regard to the places in which birds breed, and consequently not more so with regard to the mode of placing their nests, however accurate he may be in the descriptions of the birds themselves. Wilson, on the other hand, says, that in America they build in trees; and assemble in greater numbers in the same breeding-place than even the common heron. His account of their manners is unquestionably the best, not only in point of correctness, as being obtained from his own observation, but as it combines the whole manners of the bird in one very well-drawn picture. We shall therefore quote his description, and then offer a remark or two on some differences which have been observed in the nesting-places of birds belonging to the same, or at all events to very nearly allied species on the eastern continent and in America.

"The night heron," says Wilson, "arrives in Pennsylvania early in April, and immediately takes possession of his former breeding-place, which is usually the most solitary and deeply shaded part of a cedar swamp. Groves of swamp oak, in retired and inundated places, are also sometimes chosen, and the males not unfrequently select tall woods, on the banks of the river, to roost in during the day. These last regularly direct their course, about the beginning of evening twilight, towards the marshes, uttering in a hoarse and hollow tone the sound *qua*, which by some has been compared to that produced by the retchings of a person attempting to vomit. At this hour also all the nurseries in the swamps are emptied of their inhabitants, who disperse about the marshes, and along the ditches and river shore, in quest of food. Some of these breeding-places have been occupied every spring and summer from time immemorial by from eighty to one hundred pair of *qua*-birds. In places where the cedars have been cut down for sale, the birds have merely removed to another quarter of the swamp; but when personally attacked, long teased, and plundered, they have been known to remove from an ancient breeding place in a body, no one knew where. Such was the case with one on the Delaware, near Thompson's Point, ten or twelve miles below Philadelphia; which, having been repeatedly attacked and plundered by a body of crows, after many severe rencontres, the herons finally abandoned the place. Several of these breeding-places occur among the red cedars on the sea beach of Cape May, intermixed with those of the little egret, green bittern, and blue heron. The nests are built entirely of sticks in considerable quantities, with frequently three or four nests on the same tree. The eggs are generally four in number, measuring two inches and a quarter in length, by one and three quarters in thickness, and of a very pale light blue colour. The ground or marsh below is bespattered with their excrements, lying all around like whitewash, with feathers, broken eggshells, old nests, and frequently small fish, which they have dropt by accident, and neglected to pick up. On entering the swamp in the neighbourhood of one of these breeding-places, the noise of the old and the young would almost induce one to suppose that two or three hundred Indians were choking or throttling each other. The instant an intruder is discovered, the whole rise in the air in silence, and remove to the tops of the trees in another part of the woods, while parties of from eight to ten make occasional circuits

over the spot, to see what is going on. When the young are able, they climb to the highest part of the trees; but, knowing their inability, they do not attempt to fly. Though it is probable that these nocturnal birds do not see well during the day, yet their faculty of hearing must be exquisite, as it is almost impossible, with all the precautions one can use, to penetrate near their residence without being discovered. Several species of hawks hover around, making an occasional sweep among the young; and the bald eagle himself has been seen reconnoitring near the spot, probably with the same design."

Such is the description of the manners of these birds, by perhaps the most observant and felicitous describer that ever lived; and it unquestionably points to habits very different from those mentioned even by what are considered the most accurate of European naturalists. Still, it by no means follows, from this difference of the nesting-place, that the night heron of America, and that of Europe, are different species, or even different varieties. Particular nesting-places are not the grand inducements which birds have to resort to certain places for the purpose of breeding. Food for themselves and their brood is the grand matter, to which every thing else must be subservient. This being the case, it follows as matter of course, that the birds must build in such accommodation as the locality which abounds in food affords them. If there are no trees in or sufficiently near the marshes, of course they cannot build in trees, however strong that instinct might be if there were the means of gratifying it. We believe that there is no wild duck, breeding in any part of the eastern continent, which places its nest any where except under a bush, or more frequently in a close tuft of aquatic plants; but there are many of the American species, breeding far to the north, which are known to breed habitually in the short bushy trees with which the northern marshes of America abound; and so much has this style of building become part of the general instinct of the birds, that some which were kept at the London Zoological Gardens, would not breed until posts were erected, with boxes on the top, as substitutes for the trees. Even in what is mentioned by Temminck, there is a sort of evidence that the night herons of the East would breed in trees if they could find such to breed in; for he remarks, that they breed under or in bushes, and rarely in tufts of rushes. Why the nest, in such situations, may be in many cases on the ground under the bush, is easily explained; for the bushes which grow on the margins of such marshes as afford no trees, are generally so weak and pliant that they could not support the nest of a heavy bird; and we know of no instance in which a bird places her nest so as that the weight of herself and her eggs would bring it down.

The remarkable difference between the breeding-places of apparently the very same species of birds, in the same continent, is a matter which ought to teach us a little caution as to what circumstances we are to consider as essential portions of the character of a bird, and what are to be regarded only as local or accidental, and, as such, admit of change with change of locality. It is very probable that the positions of nests, and the materials of which they are formed, have been by far too much regarded as constant characters of birds; and therefore it would be very desirable to know how any one species manages matters in these respects in countries affording very dif-

ferent situations and materials, before we come to any positive conclusion on the subject. In this respect, the case of the night herons is a very important one; and this is the reason why we have gone into it at so much length, and we shall now give some account of the appearance of the bird.

In doing this, we may remark, that there is a very considerable difference in size between the night heron as it occurs on the eastern continent, and as it occurs in America; and that there are some differences in this respect in different parts of the eastern continent. Twenty-two inches is the usual length in Europe, and twenty-four inches the usual length in India, where the bird is by no means rare. In America the length is twenty-eight inches, and the bulk of the body and extent of the wings are large in proportion, the latter measuring four feet from tip to tip.

This difference of size shows pretty clearly in what country the bird is most at home. America is decidedly the most favourable to it, and India is more favourable than Europe. Therefore, whatever habits the bird may have in America are justly to be regarded as its natural habits; and as one of the natural habits in America is to breed in trees, and collect in large societies in the same breeding-place, we may very safely conclude that this is the natural habit of the bird; and that where this habit is not accommodated, the bird is in so far put out of its way, and the result is, that it is dwarfed in its dimensions. This point may be considered as demonstrated in the case of the species in question; and a little careful observation in different places, and just comparison founded on this observation, would render the same principle applicable to any species of bird, or indeed to any other living production of nature. This is of far more value than any individual description, because it leads us immediately to the connection that exists between the living world and the rest of nature; and this is the most valuable instruction which natural history can give us.

The bill (in the American bird) is four inches and a quarter in length, from the angle of the gape to the point; the naked space from the eye to the gape bluish, and that round the eyes deep purple. The eye is large, being three quarters of an inch in diameter; the iris bright pure red, and the pupil black; the legs and feet are pale yellowish cream-colour, and the claw of the middle toe is toothed on the inner side. The crest on the head and hind head are deep blue, with green reflections, but the forehead and a bar across the eye are white. Pendent from the nape there are three very narrow and tapering white feathers between eight and nine inches long; the webs of these are concave, or curled inwards on their under sides, so that each embraces the one below it; and so difficult is it to derange the form of this graceful crest, that even if these feathers are ruffled in the skin of the dead bird, shaking them two or three times will bring them into their natural position. In consequence of this the three feathers appear only as one, and the bird has the power of erecting them when excited. The cheek, neck, and lower parts are white, with a tinge of yellowish cream colour, and with very pale ash-colour under the wings. The back and scapulars are of the same rich blue with green reflections to which we alluded as occurring on the head. The rump, the tail and its coverts, and the whole of the wings, are very pale ash-colour. Thus attired, the night heron, notwith-

standing its unmusical voice, is really a very beautiful bird; and from the number of noxious creatures that it destroys, it is very far from being a useless bird.

The female differs in nothing from the male bird, excepting that perhaps the ash-colour on the wings is a little darker; and those who have described the female as being without the crest have evidently confounded it with the young. In the young of the year the colour on the upper part is very deep brown, streaked with reddish white, and having triangular spots on the back and wings, which extend from the middle of the feathers to the extremity. The quills are dusky black, with a white spot on the tip; the belly white, with dusky streaks; the iris bright orange, and the legs and feet pale green. These colourings differ so much from those of the mature bird, that unless the fact had been ascertained by actual observation, the identity of the species would not readily be believed. In the second year the brown on the head and back still remains, but the whitish spots are smaller and less numerous. The spots on the wing-feathers are also smaller, and ash-colour appears on some of the quills. There is also generally a greenish tinge on the scapulars, and the under parts are whiter than in the birds of the year; the bill is of a blackish brown, the iris reddish brown, and the feet slightly greenish.

It does not appear that there is any difference of colour in birds of the same age, as they have been seen in Europe, in Southern Asia, and in North America; and indeed the only difference at all perceptible is that of size, already mentioned; and we believe that in this respect they are much more uniform in America than in Europe, which is another reason for concluding that they are more at home there.

Such are the outlines of a few of the more remarkable birds in the very numerous and highly interesting family of the herons. Had our limits permitted, we might easily have extended the list, though the extension would have, after all, been little else than so much mere description of shape and colour, which, considered in themselves, are matters of minor consequence. The species which we have enumerated, go, we believe, to the more striking characters and habits of the genus, whether as one, or as divided into sections.

HERON'S BILL is the *Erodium*, a genus of plants, defined and described by Le Heritier.

HERRING (*Clupea*, or rather perhaps *Clupeidae*, the herring family). A genus of malacopterygious, or jointed-rayed fishes, with abdominal fins; and, in an economical point of view, one of the most valuable of all the many inhabitants of the waters. They hold nearly the same place among fishes permanently inhabiting the sea, as the salmon family do among those who live in fresh water, or alternately in the salt water and the fresh; and though none of them at all approach the size of the more important of the salmon, and are not so much prized, their numbers, and the various ways in which they may be preserved, as well as the length of time that the preserved ones may be kept, and the distance to which they may be carried, add greatly to their value as an article of human food.

In addition to the characters already mentioned, it may be stated that the herring family differ from that of the salmon in having no adipose or fatty dorsal fin, but agree with the trouts in having the inter-

maxillary bones without pedicles. Their bodies are always very scaly; the greater number have an air-bladder and numerous caecal appendages to their intestines. They are chiefly sea fishes, but some peculiar ones are found in large fresh water lakes, and others ascend the rivers at least as high as the termination of the brackish water. The species, as well as the individuals, are very numerous; and they have sometimes been divided into different genera, though such division does not appear to render the study of them any easier, and therefore we shall not pay much attention to it. We have already given some account of two of the species, namely, of the *shad*, in the article *ALOSA*; and another, the *ANCHOVY*, we noticed under that title. We purpose in the present article very briefly to mention the more remarkable of the remaining ones.

THE HERRING (*C. harengus*). This is a fish so familiar to everybody that no formal description of it is necessary; and yet, strange to say, it is one respecting which very many absurdities have been written, and that even by naturalists who in some respects are worthy of commendation. The old opinion was, that these fishes, which retire from our shores at certain seasons of the year, and return to them at others, swam off *en masse* to the polar seas during the winter months, remaining there and enjoying some incomprehensible benefit from a frozen canopy over them, until the returning season, which in the commencement of winter had sent them from cold to colder, brought them back to warmer habitations toward the end of summer. What they may have done, or could have gotten, in the extreme north during the intensity of the cold, for they continue on some parts at least of the British shores till nearly the end of the year, the manufacturers and retailers of these most singular allegations have not apparently felt themselves bound to say. It will however be but right to hear Pennant on the subject, because he gives the story with all due pomp and circumstance. The opening of course alludes to their advance from the north, when, like so many Goths and Vandals of the ocean, they come to overrun and take possession of our more hospitable seas:—

"This mighty army," says Pennant, "begins to put itself in motion in the spring. We distinguish this vast body by that name; for the word herring is derived from the German *Herr*—an army, to express their numbers. They begin to appear off the Shetland islands in April and May. This is the first check this army meets with in its march southward. There it is divided into two parts: one wing of those, destined to visit our coasts, takes to the east, the other to the western shores of Great Britain, and fill every bay and creek with their numbers; others proceed towards Yarmouth, the great and ancient mart of herrings; they then pass through the British Channel, and after that in a manner disappear. Those which take to the west, after offering themselves to the Hebrides, where the great stationary fishery is, proceed towards the north of Ireland, where they meet with a second interruption, and are obliged to make a second division: the one takes to the western side, and is scarcely perceived, being soon lost in the immensity of the Atlantic; but the other, which passes into the Irish sea, rejoices and feeds the inhabitants of most of the coasts that border on it. These brigades, as we may call them, which are thus separated from the greater columns, are often capricious in their motions;

and do not show an invariable attachment to their haunts." Now so far is this from being the true state of the case, that herrings are very rare in the polar seas at all seasons of the year; and the few that are met with in the extreme north belong to a smaller and much less valuable variety than that which is caught in such numbers on the British shores. In truth, the habit of the herrings, and, generally speaking, of the whole herring family, does not differ much in its great principles from that of the salmon, only the species with which we are acquainted do not ascend the rivers as the salmon do, though some of them approach farther up the estuaries than others. Their proper pastures, when their only objects are feeding and recovering their strength, after having been exhausted by the process of breeding, are the deep waters of the sea, at a considerable distance from the land. They are however, to a certain extent, surface fishes: and surface fishes, as we might expect, do not deposit their spawn under a very great depth of water; because a certain degree of action of the solar heat and light appears to be necessary for quickening the eggs into life; and not only this, but the maturing of the spawn within the bodies of the animals appears to require an approach towards the shores. Hence the herrings arrive off the coasts for some time before they begin to deposit their spawn; and this is the time at which they are most valuable for food, and caught in such numbers at the different fishing stations. Whether they breed every year, that is, whether, after having deposited their spawn for one year, they are ready to return with an equally productive load the next year, is a question which we cannot determine. It is not very probable that so excessive a production can go on year after year; but as we cannot follow those migratory fish which disappear from our coasts at certain seasons into the depths of the ocean, we cannot speak positively on this part of the subject. We may rest assured, however, that there is no very great migration in latitude in herrings or in any other species of fishes which inhabit the sea. It is indeed said that whales not only migrate, but migrate almost from the one pole to the other in the course of the year; but it will be recollected that whales are not only warm-blooded animals, but animals of comparatively high temperature; and that they not only come to the surface to breed, but feed with part of the body above water. Therefore we can easily suppose that the rigour of the polar winter might drive such an animal after the sun into more southerly latitudes. This, however, implies no necessity of migration in fishes, which keep constantly below the water, and are not only in their own temperature, but experience very little change in that of the medium in which they swim during the whole year. In our seas there is a slight difference of temperature of the surface water in summer and in winter; but it is doubtful whether this reaches to any considerable depth, and therefore we can assign no cause why herrings or any other fishes should migrate much in latitude.

The most rational opinion, and indeed the only one which has any thing like reason or philosophy in it, is that those fishes inhabit the deep water around our coasts at all seasons of the year when they do not approach near the land; and that their object in approaching the land is that of breeding as above stated. It is well known that they deposit their spawn on our shores, beginning in some instances in

the month of October, in others not till November and there are instances in which the operation is not wholly completed until nearly the end of December. When it is entirely over, and the fishes are on their return to the deep water, their flesh is exhausted and tasteless, and even unwholesome, and they are proverbially known by the name of "shotten herrings," which is a common expression for any thing worthless; but as long as they remain on the coast without having actually spawned they are in good condition; and we have certainly seen good herrings selling at the very moderate rate of forty a penny as late as the third week of December.

They approach the land in vast shoals, often extending many miles in length and breadth, and probably fathoms in depth; and sometimes, when those shoals are caught in severe gales, the fishes are stranded in numbers beyond all imagination. This usually happens during the violent gales which frequently occur about the time of the autumnal equinox, for that is the period of the year at which herrings approach our shores in the greatest numbers. In some of the lochs or arms of the sea, on the west coast of Scotland, they have often been cast ashore in such numbers that they were chopped up as manure for the land; and the writer of this article remembers a case, on the east coast of Scotland, when, during a strong gale from the north-east, an entire shoal was shipwrecked. It does not appear that herrings retreat in any considerable numbers to the cod-banks in the southern part of our eastern sea; and there are two reasons why they should not: in the first place, the water there is comparatively shallow; and, in the second place, the cod are most ravenous fishes, and would doubtless make terrible havoc of a shoal of herrings if it should come within their locality. Hence the greater number of those herrings which reach the more southerly parts of our east coast certainly do come from a little way north, and, in their passage, they keep between the cod-banks and the land; and as, during their migration shoreward, they come pretty near the surface, it is natural to suppose that, along with the surface-water, they should, to some extent at least, drift before the wind. In the case to which we allude, which occurred at the town of Crail, at the eastern extremity of the peninsula of Fife, a gentleman, on whose veracity we can rely, was spending a day with a friend at the outskirts of the town. The bellman passed, making a violent clatter, with not the most musical of all instruments, and then proclaimed, with stentorian voice, that any one who chose to go to the shore, meaning thereby the harbour of Crail, would get a cartload of live herrings for a shilling. This passed without much notice; but by and by the bellman again came round, proclaiming, that any one who pleased to resort to the shore of Crail would get a cartload of live herrings for nothing. The second announcement, of course, excited some speculation; and it was soon followed by a third one, that any one who would be kind enough to go to the shore of Crail would get a shilling for taking away a cartload of live herrings. This seemed something very extraordinary, and the party set off for the shore accordingly. Upon arriving there, they found that a shoal of herrings, on their way probably to the Frith of Forth, and the sandy beach between North Berwick and Dunbar, which are understood to be favourite places for the depositing of the spawn, had been driven inside the

reef of the Carr-rocks, and so stranded, and that, left by the ebb-tide, they lay in countless thousands for at least a mile and a half or two miles along the shore. The reason for the announcement was a fear on the part of the authorities in Crail that such a quantity of animal matter remaining to putrify on the beach would taint the atmosphere and cause disease.

At that time there was of course no danger; for though herrings, as is the case with all surface-fish, and with this family in an especial manner, die very soon after being taken out of the water, yet many of them were alive, and less injured than if they had been taken in the usual way, of being entangled in nets by the gill-lids. Thus they were there absolutely as a mine of wealth; but, unfortunately, the people could not avail themselves of them to the full extent of their value. There are salt-works, that is, works for obtaining salt by the evaporation of seawater, at no great distance, but, unfortunately, the impolitic, and, in cases like this, the most iniquitously cruel duty on salt then existed; and, though we believe there was a drawback of the duty upon salt which had been applied to the curing of fish, there was no warehouse bonding, or any other means by which a stock could be kept without actual payment of the duty in the first instance; and this was tantamount to a positive enactment that no stock should be kept.

There cannot be a more severe reproof of that ministerial cupidity, which, for the gratification of ambition, and the most unholly purpose of deluging the earth with human blood, ignorantly lays taxes upon everything, without knowing or caring what may be the consequences, than such a case as this. There was an immense quantity of human food, in the very finest condition, cast on the shore, without contrivance or labour on the part of man, as if it had been a miraculous instance of the bounty of Heaven; and yet the people could not avail themselves of that bounty because of the duty on salt! At the same time there was a Board for the Encouragement of the British Fisheries, with well-paid commissioners, and there were bounties given to *certain* successful prosecutors of the fishery. Fortunately for us, those times of "the blackness of darkness" in legislation have, in some measure, gone by, and perhaps the period is not very remote when they will be numbered among the fables of antiquity, which all wonder at, but none believe. In this case there was probably, however, more absolute loss from the want of salt than the whole salt-duty of Scotland amounted to in a dozen years. It may be said that the people of Crail could have kept a stock of salt, well knowing that, if a shoal of herrings should ground upon their coast, and they should use the salt in curing them, they would get the drawback. But this same system of drawback, while it leads to many acts of villany, is one of the most complete extinguishers of industry and enterprise that can be imagined. If there were no drawback, people would include the duty among the other costs of production, and so accommodate the article to meet contingencies, much in the same way as if there were no duty; but there never will be a surplus of that upon which a payment has been made, to be got back again under circumstances which are contingent; and thus the drawback has a more mischievous effect upon any manufacture than the same amount of duty without any drawback. Therefore, the sooner that all such mischievous laws are repealed the better.

In the cases alluded to, the people did what they could; they used all the salt in the towns and places adjoining; and they made signals, and sent messages, so that light craft came from some other places, and carried off part of the herrings in bulk; but the fish are too tender for such treatment, and only a small quantity could be taken, as there was enough to load a navy; and, therefore, the farmers of the neighbourhood carted off the far greater part, to be worked up in compost as manure.

Though there is no reason to believe that the herrings make any longer voyages than from the deep waters to the shore, to mature and deposit their spawn, and back again when that operation is completed; yet they are, to our apprehension, very capricious,—that is to say, they come in multitudes to certain parts of the coast for a greater or smaller number of years, and again totally abandon it, nobody can tell why. Of course there is no caprice in this; for, like all other occurrences in nature, it may have a natural cause; and the probable one is that the herrings, by resorting to one particular spot in such immense shoals as they do, exhaust that spot of the proper food for themselves and their offspring; and are under the necessity of seeking another haunt, until the store again accumulates in such quantity as to be adequate to their wants. Fat bottoms, where there is an eddy, or one current running against another, and consequently a deposit, appear to be the places which they prefer; and hence, the herrings in Loch Fyne, and some of the other inlets of the Atlantic, which have the middle of considerable depth, but the bottom rich toward the shores, are much larger and finer than those taken in water where there is little stagnation, and, consequently, little deposit. On the east coast we find the herrings richer in flavour in proportion as they are nearer to the banks, though, for the reason which we have already assigned, it is not probable that they naturally resort to those banks where cod shoal, although cod are much more bottom fishes than herrings. The exhausting of their food at any particular spawning-place is, however, the only natural reason that we can assign for the apparent caprice of the herrings; and we find it confirmed, or, at all events, rendered more probable, by the conduct of some other animals both of the sea and the land. Haddocks are not quite so capricious as herrings; but they often quit a particular spot after being abundant upon it for years. Salmon also desert rivers, not only in consequence of the quantity of deleterious matter in them (which is probably the cause of their having deserted the Thames), but also when only gravel is discharged into the stream. In forming the Caledonian canal, it was found necessary partially to change the bed of the river Ness. The cutting thrown into it was clean gravel; but in such quantity that, though the water was not at least very turbid all the way to the sea (about two or three miles), there was a constant deposit of gravelly matter on the bottom; and the salmon, in a great measure, deserted the river. The only probable cause of this desertion was that the gravel covered up the food either of the salmon or of their fry, most probably of the latter. We must not wonder that a salmon should cease to come for the purpose of spawning to a place where its young cannot find food; for, in all cases where the parent animal does not attend to the young, there is an instinct which guides

the parent to the proper *nidus*, with far more certainty than the reason of man can do it. These appear to be chief natural causes of the apparent capriciousness of the herrings, in respect of locality; and we have stated them at some length, because they will, with modifications for the several races, apply to every fish which has the same habit.

Some explanation of this kind is necessary, also, on account of the prejudices which exist on the subject. The disappearance of any valuable species of fish from a part of the coast on which they have been abundant for some time, is one of the most severe calamities that can befall the inhabitants; as great, in some instances, as if the blight of total sterility were to be sent upon the earth. This being the case, and more the case in proportion as the land is poorer, and the people more dependant on the sea, (which is saying, in other words, that they are very superstitious,) it is very natural that the people should assign causes for these apparent caprices; and, under the circumstances, it is hardly possible that they should assign any but superstitious and absurd ones. But there are perhaps no evils more prone to growth and spreading than prejudices; and thus, when they are entertained upon any one subject, they very speedily taint the whole character.

Some of the prejudices which are entertained respecting the disappearance of herrings from different localities on the British shores, are so very curious, notwithstanding their absurdity, that we shall notice them; and we cannot do better than by quoting from the late Dr. McCulloch, and we shall quote as from Mr. Yarrell's admirable work on British fishes, for the sake of introducing an Irish anecdote mentioned by that gentleman in supplement to the Scotch absurdities. "Ordinary philosophy is never satisfied," says Dr. McCulloch, "unless it can find a solution for every thing; and is satisfied, for this reason, with imaginary ones. Thus, in Long Island, one of the Hebrides, it was asserted that the fish had been driven away by the manufactory of kelp; some imaginary coincidence having been found between their disappearance and the establishment of that business. But the kelp fires did not drive them away from other shores, which they frequent and abandon indifferently without regard to this work. It has been a still more favourite and popular fancy, that they were driven away by the firing of guns; and hence this is not allowed during the fishing season. A gun has scarcely been fired in the western islands, or on the west coast, since the days of Cromwell; yet they have changed their places many times in that interval. In a similar manner, and with equal truth, it was said that they had been driven from the Baltic by the battle of Copenhagen. It is amusing to see how old theories are revived. This is a very ancient highland hypothesis, with the necessary modification. Before the days of guns and gunpowder, the highlanders held that they quitted coasts where blood had been shed; and thus ancient philosophy is renovated. Steam-boats are now supposed to be the culprits, since a reason must be found; to prove their effect, Loch Fyne, visited by a steam-boat daily, is now their favourite haunt, and they have deserted other lochs where steam-boats have never yet smoked." "A member of the House of Commons, during the session of 1835, in a debate on a tithe bill, stated, that a clergyman having obtained a living on the coast of Ireland, signified his intention of taking the tithe of fish;

which was, however, considered to be so utterly repugnant to their privileges and feelings, that not a single herring had ever since visited that part of the shore!"

Herrings, besides coming in great numbers to our shores, are exceedingly prolific; and the spawn being deposited in the end of autumn or the early part of winter, much about the same time as that of the salmon, quickens early in the spring; and, as the summer advances, the fry are found in countless multitudes along all the shores where the bottom is shelving, and the water shallow for some distance. Though the shoals of herrings are met with at particular points only it is probable that they deposit their spawn along the whole line of the coast wherever the bottom is fit for the purpose; and thus immense quantities of fry are met with in places where there is no fishing. Thus, for instance, herrings are very rarely caught in the Tay; and yet, when stake-nets were erected in the estuary of that river for catching salmon, such multitudes of herring fry, or "herring-soil," as they are called generally, on the east coast, though with various pronunciations of the last syllable, got entangled in the nets, that at low water they were sometimes found lying ankle deep; and without any entanglement they may sometimes be taken in great quantities by simply letting down a basket and drawing it up again. So common indeed are they, that it is scarcely possible to use a small meshed net during the summer upon any part of the coast without capturing numbers of them; and the juvenile fishers at the points of piers, and jetties, and other situations where there runs of tidal water, catch them indiscriminately with the fry of the coe fish. They retire from the narrower parts of the estuaries at the end of summer, though in some of the broader ones they remain during the autumn, and do not rove far from the coast during the winter. Indeed it is by no means improbable that if the movements of grown herrings in the sea were properly traced, it might be so managed that they might be taken in a condition fit for use at all seasons of the year, at least if, as we are inclined to believe, the spawning is not annual.

Herrings are captured by means of what are called drift nets, that is, nets which are left in the sea, suspended from the surface, and descending only to a moderate depth. This is the usual method of catching all the surface fishes which swim in shoals, such as mackerel and pilchards, only the meshes of the net vary with the kind of fish. In such nets the fishes are not enclosed, but entangled in the meshes through which they attempt to pass, but are not able, neither can they retreat, as the threads of the mesh catch hold of their gill-covers, and thus they are often suffocated while in the net. These nets often extend to a great length, many miles belonging to the same proprietor in the larger fisheries; and these fisheries can be carried on to the proper extent only by persons of considerable capital. A proper equipment of nets, boats, and busses, with the men requisite to work them, requires an outlay of from fifteen to twenty thousand pounds; and after all, the fishery, at least that for sea fishery where such extensive nets are used, is in a great measure a lottery. Owing to the capricious habit of the fish, they may not come to the spot where the net is put down; and on the other hand, as the best fishing is about the time when the autumnal gales are most severe, the nets may be drifted out to sea and lost, by the action of the wind

upon the floats by which the drift-rope that supports the net is buoyed up. When a loss of this kind does occur it is peculiarly serious, as being the loss of the season as well as the property; and as the prevention of such losses, especially on the coasts of the Highlands, where the autumnal winds are very inconstant, requires a great deal of experimental knowledge of the weather, and intimate acquaintance with the various motions of the sea, the fishery cannot be conducted by adventurers, or indeed by any one who has not been bred to it on the spot; and if half the sum which has been given in bounties had been expended in training men for the task, there is no doubt that great advantage would have thence arisen.

In order to show the advantages of this fishery, we shall give an abstract of the returns of the whole produce of the fishery for 1815, and the four years following. "By the report of 1815, it appears that the quantity gutted and cured was 105,372 $\frac{1}{4}$  barrels. By that of 1816, it amounted to 135,981 barrels, being an increase in one year's fishery of 30,608 $\frac{3}{4}$  barrels. The quantity cured ungutted, in the former period, was 54,767 barrels; in the latter 26,670 $\frac{3}{4}$  barrels, being a decrease of 28,096 $\frac{1}{4}$  barrels. The total quantity brought under the view of the officers in 1815 was 160,139 $\frac{1}{4}$  barrels. In 1816 it was 162,651 $\frac{1}{4}$  barrels, being an increase on the whole of 2,512 $\frac{1}{4}$  barrels. The quantity branded for bounty in 1815 was 88,376 barrels. In 1816 it was 116,436, being an increase of 33,060 barrels. The exports on the whole in 1815 exceeded those of 1816; but the gutted herrings exported in the latter year exceeded those of the former by 12,606 $\frac{1}{2}$  barrels. In the year 1817 the total quantity caught was 192,343 $\frac{1}{2}$  barrels, being an increase of 29,691 $\frac{1}{4}$  barrels. In the same year the quantity branded for bounty was 140,018 $\frac{1}{4}$  barrels, being an increase of 23,582 $\frac{1}{2}$  barrels. The quantity exported in 1817 was 138,628 $\frac{1}{2}$ , being an increase of 30,940 $\frac{1}{4}$  barrels. In the year 1818 the total quantity caught was 227,691 barrels, whereof 204,270 $\frac{1}{4}$  were cured gutted, and 23,420 $\frac{3}{4}$  ungutted; being an increase in the total quantity of 35,347 $\frac{1}{2}$  barrels, and of 48,494 $\frac{1}{4}$  in the quantity gutted; while there was a decrease in the quantity cured ungutted of 13,146 $\frac{3}{4}$  barrels. In this year the quantity found entitled to bounty was 183,089 $\frac{1}{4}$  barrels, being an increase of 43,071 barrels. In the same year the total quantity exported was 162,339 $\frac{1}{2}$  barrels, whereof 148,147 $\frac{1}{2}$  were gutted, and 14,192 ungutted; being an increase in the total quantity of 23,711 barrels, and of 32,667 in the quantity gutted; while there was a decrease in the quantity ungutted of 8956 barrels." The vast numbers in which these fishes are taken, and the readiness with which they find a market, more especially in the warmer countries, point out how very important they are to this country, and how worthy their history is of being studied with the utmost attention.

It may seem hardly necessary to give a description of a fish so well known as the herring; but we shall quote Mr. Yarrell's description, with a view both to show how a fish ought to be described, and how admirably this excellent naturalist has described this one, and indeed all others; and the specimen will no doubt induce such as are fond of the study of fishes, a study which deserves far more attention than it generally meets with, to take Mr. Yarrell as their guide to the whole finny tribes of the British waters. "The length of the head," says Mr. Yarrell, "compared to the length of the body alone, without the

head or caudal rays, is as one to four; the depth of the body, compared to the whole length of the fish, as one to five; the commencement of the dorsal fin half way between the point of the upper jaw and the end of the fleshy portion of the tail; the longest ray nearly as long as the base of the fin; the pectoral fin rather large compared to the size of the other fins. The ventral fin arises considerably behind the line of the commencement of the dorsal fin—this fin is small, with elongated axillary scales, its origin half way between the point of the lower and the end of the short central caudal rays; the anal fin begins half way between the origin of the central and the end of the fleshy portion of the tail, and extends over half the distance between its origin and the end of the fleshy portion, thus occupying the third quarter division of the distance between the origin of the ventral fin and the end of the fleshy portion of the tail; the rays very short; the tail considerably forked; the outer rays as long again as those of the middle; the fin rays in number are, dorsal fin seventeen rays, pectoral fin fifteen, ventral nine, anal fourteen, caudal twenty, spine consisting of fifty-six vertebrae, but the rays vary in some specimens to nineteen dorsal, seventeen pectoral, nine ventral, sixteen anal, and eighteen caudal. The lower jaw is by much the longer, with five or six small teeth extending in a line backwards on each side from the anterior point; four rows of small teeth on the central upper surface of the tongue; a few small teeth on the central portion of the upper jaw, and the inferior edges below the gape finely serrated; the eye large; its diameter, compared to the length of the head, as two to seven, and placed at the distance of its own breadth from the end of the nose; the dorsal and abdominal lines of the body slightly convex; the belly carinated, but not serrated; the scales moderate in size, oval, and thin. The upper part of the fish a fine blue, with green and other reflections when viewed in different lights; the lower part of the side and belly silvery white; cheeks and gill-covers silvery, exhibiting the appearance of extravasation when the fish has been dead twenty-four hours; dorsal and caudal fins dusky; the fins on the lower parts of the body almost white."

LEACH'S HERRING (*C. Leachii*). We are indebted to Mr. Yarrell for the first distinct account of this variety, though it had been previously noticed by others that there were some differences in herrings. This species differs from the common one in the shape being much deeper in proportion to the length, and more curved in the line both of the back and the belly. The eye is also much larger, and the scales smaller; the dorsal fin also is not placed quite so far behind the centre of gravity, so that when this fish is tried by the usual test of distinguishing a sprat from a herring, by the drooping of the herring's head when held by the dorsal fin, this one does not droop so much as the other. This species is met with on various parts of the British coasts; but, so far as is decided, not in such numbers in any one locality as the common herring. It may be, however, that this is the fish which is sometimes taken in good condition and full of roe in the middle of winter; and if so, there is a chance that, if proper attention were paid to this fishery, the herring might be obtained fresh for at least six months of the year; for this one comes in season as soon as the common herring goes out. The herring fisheries in the western and eastern seas of the north part of the island alternate with each other,

that of the west being over before the eastern one comes on; and this would lead to a conclusion that there is a difference of species, or at all events of variety, between the herrings of those two seas. The usual way of explaining this was derived from the absurd notion of the annual pilgrimage of herrings from the pole; and as that must be abandoned, we can only suppose that the herrings which come near the land at different seasons in places so little different from each other spawn at different seasons. It is probable that the common herring is the herring of the Atlantic, though the other is certainly met with there also; and that the present species is the herring of the north seas, which inhabiting water of a colder temperature, is later in bringing its spawn to maturity. These however are points respecting which there must be a good deal farther examination before the difficulty can be cleared.

**THE PILCHARD** (*C. pilchardus*). The pilchard is a more southerly and more local fish than the herring; being, as a British fish, found chiefly on the Cornish coasts, and it is rare indeed that one is met with beyond Dover, or even in the narrow part of the channel. The old story assigned the same pilgrimage to the pilchard as to the herring; but it is now well ascertained to be resident on the coast of Cornwall all the year round, only it follows the instinct of the genus, by coming to the shore for maturing and depositing its spawn, and returning again to the deep water when these purposes are accomplished. In the cold months, they remain in the deep water; and they are a little capricious in the times of their appearance in numbers near the land, though not so much so with regard to places as the herrings. Sometimes they come as early as March and April; but July and August are the times of their regular appearance, the great fishing being in August and September, at which times they are taken both with the sean and drift net. They appear to deposit spawn very irregularly at different times of the summer. The motions of the shoals of pilchards are very capricious; and therefore, though they are found on the same grounds year after year, a good deal of experience is requisite in order to be successful in the capture of them.

The description of the pilchard fishery given by Mr. Yarrell is highly interesting, but our limits do not admit of quoting. The most interesting mode is perhaps that with the sean. This is generally used in the sandy bays, and the fish, which are exceedingly timid, are driven into such a situation as that they can be enclosed by the net. When a large haul of fishes are enclosed in the net, and brought to the surface, the splutter and noise which they make in attempting to escape is very great; but when the large sean is properly worked, and secured by grapnels, the fish can be taken from it in portions at a time, so that if the quantity enclosed is very great, the removing of the pilchards from the sean may occupy a whole week. The number of these fish which is captured is often very great. Two thousand or three thousand hogsheds have been taken by one sean in the course of a year; and as a hogshed contains from two thousand to five thousand fish, the number is immense. Twenty-five millions of pilchards have sometimes been landed at one port in a single day, which is more than a pilchard a piece to every man, woman and child, in the three kingdoms; and as this is only one out of three or four ports at which this

fishery is carried on, at the south-west of England alone, it is not too much to say, that local as the pilchard fishery is, it might be made to support while it lasts the whole people of the united kingdom.

Pilchards also occur in great numbers on the south-west of Ireland, the principal fishery being in Bantry Bay; and they are found, though less abundantly, on the south-east and east of Ireland. They are likewise met with on the French coasts, and on those of Spain, but less abundantly on the latter; thereby proving that the fishes are very local, and do not extend into the warm latitudes.

The pilchard is thicker and smaller than the herring; the scales are large, they are periodically shed, and have a fringe at the posterior edge, which enables them to take a powerful hold on the water when swimming. The dorsal fin is nearly triangular; and its posterior edge is nearly over the centre of gravity, so that when a pilchard is held by this fin, the head rises, and the tail droops down, which is the very reverse of what happens with the herring. In the average of pilchards there is one ray more in the dorsal fin, one more in the pectoral, one less in the ventral, four more in the anal, and one less in the caudal, and there is one vertebra less in the spinal column. It is probable though however, that the number of rays in the fins are subject to variation, as is the case with the herring. The mouth is small and toothless, with the under jaw projecting beyond the upper; and the food is understood to consist of the smallest insects and crustacea which inhabit the sea. The eyes are whitish yellow, the gill-covers bright yellow, the upper part bluish green, the sides and belly silvery, and the dorsal and caudal fins dusky.

**THE SPRAT** (*C. sprattus*). The old opinion that the sprat is the young or fry of the herring, is now exploded by all who are in the least acquainted with the habits and characters of fish, but it still continues a matter of popular belief in many places. Indeed, in a family of fishes which possess so much family likeness, and yet differ so much in size, it was perhaps natural to suppose, in the times of ignorance, that the smaller ones were the young of the larger. There is something in the succession of herrings and sprats which may lead vulgar belief this way, though to those who reflect on the matter the conclusion to which it leads is exactly the opposite. Sprats come near the shores in great numbers after the herrings are gone, but seldom if ever so long as these remain; thus it was natural to conclude that the offspring followed the parents. But then the sprats come to the shores for the same purpose as the herrings; and we never find the young of any species of seasonal fish making their appearance in numbers, or of a size worth catching, until a considerable time after the parent fishes have taken their departure. The herrings disappear in the beginning of winter generally, and the young herrings are not found till the end of spring, or the beginning of summer. Sprats appear in the beginning of winter, and continue the whole winter through; and though there is no doubt that the young sprats are hatched some time about midsummer, yet they are not so much observed as the young herrings. Though sprats are small, they are not without their value; because they are caught in vast numbers, and at a season when neither pilchard nor herring in the recent state is to be had. They are sold cheap; but when recent and dressed

with due care, they make no unsavoury meal. It is necessary, however, that they should be recent; for there are few fishes that are sooner injured by keeping than sprats.

The sprat is a fish of the east coast of Britain rather than the west, and its favourite places are the estuaries of the rivers farther upward than the herring usually comes. Thus, in the north, the herring, though plentiful on the coast of Caithness, rarely comes far into the Moray Firth; while the best sprat fishing is in the arm of that Frith which extends beyond Inverness to Beaulieu. In the Frith of Forth the herring, even when most frequent in that locality, seldom goes above Kinghorn, or even as far, while the sprat ascends to the narrows about Inch Garvie; and on this account the vulgar name in that part of Scotland is "Garvie herring," or simply "Garvie." In the Thames, again, the sprat comes about the east of Kent, and partially round the North Foreland. On the east and north-east of Ireland, the sprat also makes its appearance; but it does not resort to any part of the coast which is exposed to the full roll of the Atlantic.

In the south of England the sprat fishing begins in November; but it is earlier in the north; and the fish is less esteemed there, because fish are more abundant and buyers fewer there than in the south. Sprats are caught with small-meshed drift nets, or with stow-boats. In this case two boats have a large purse-net between them kept open to the run of the water by two beams, one above the other, and six farther apart; the depth of the whole from the surface being a matter depending on local circumstances. The current carries the sprats into this great net; and when the proper time comes, the mouth of the net is closed by raising the lower beam. "All is fish that comes into a net" of this kind,—sprats, dory, anything. The quantity taken is often immense, and as counting is out of the question, they are sold by measure, sometimes at sixpence a bushel for manure. A full-grown sprat is about six inches long, and rather more than an inch in depth. They are eaten fresh, preserved in various ways, and sometimes manufactured into counterfeit anchovies.

**WHITEBAIT** (*C. alba*). Long as this fish has been celebrated by the more *récherche* *ichthyophagi*, for its delicate flavour, and the impossibility of getting it in perfection anywhere but at the few places where it can be had recently caught, it was not until within these few years, when Mr. Yarrell investigated its natural history, that the truth was known concerning it. This may seem singular; for there is scarcely a constellation of great men, right honourable, right worshipful, right learned, or, we believe we may add, right reverend, in the British metropolis, which would not from time immemorial have considered it a ban-yan year in the calendar, if they had not got their annual feast of whitebait at Greenwich, or in the vicinity. It may be true that, as the poet sings,

"dainty bits  
Make rich the ribs, but banker out the wits;"

but still, when we consider that the most learned societies have been for so long a period doing the greatest justice to this little fish in a gastronomical point of view, it seems passing strange that none of them should have ever thought of being grateful to the little lord of the feast, and showing their gratitude by giving it a local habitation and a name upon the

scroll as a distinct species and perfect fish, instead of continuing to regard it as the young of the shad; for if they had used their eyes with half the zeal on the living fish that they no doubt displayed in their palates to the dead one, they would have seen that, if the offspring of the shad, this fish could not be legitimate. It is, perhaps, as well, however, that they let this matter alone; for we doubt very much whether any one individual, or, with great deference, any one society, however learned, could have done half the justice to the subject which has been done by Mr. Yarrell; and we, on our part, should be doing injustice both to him and to our readers if we did not quote a portion of his description, instead of substituting any thing of our own.

"About the end of March, or early in April," says Mr. Yarrell, "whitebait begin to make their appearance in the Thames, and are then small, apparently but just changed from the albuminous state of very young fry. During the fine weather of June, July, and August, immense quantities are consumed by visitors to the different taverns at Greenwich and Blackwall. Pennant says, 'they are esteemed very delicious when fried with fine flour, and occasion during the season a vast resort of the lower order of epicures to the taverns contiguous to the places where they are taken.' What might have been the particular grade of persons who were in the habit of visiting Greenwich to eat white bait in the days when Pennant wrote, I am unable to state; but at present the fashion of enjoying the excellent course of fish, as served up either at Greenwich or Blackwall, is sanctioned by the highest authorities, from the court at St. James's Palace in the west, to the Lord Mayor and his court in the east, including the cabinet ministers and the philosophers of the Royal Society. As might be expected, examples numerous and influential have corresponding weight; and, accordingly, there are few entertainments more popular or more agreeable than a white-bait dinner. The fishery is continued frequently as late as September; and specimens of young fish of the year, four and five inches long, are then not uncommon, but mixed, even at this late period of the season, with others of very small size, as though the roe had continued to be deposited throughout the summer; yet the parent fish are not caught, and are believed by the fishermen not to come higher up than the estuary; where, at this season of the year, nets sufficiently small in the mesh to stop them are not in use. The particular mode of fishing for whitebait, by which a constant supply during the season is obtained, was formerly considered destructive to the fry of fishes generally, and great pains were taken to prevent it by those to whom the conservancy of the fishery of the Thames was entrusted; but since the history and habits of this species have been better understood, and it has been ascertained that no other fry of any value swim with them,—which I can aver,—the men have been allowed to continue this part of their occupation with little or no disturbance, though still using an unlawful net."—Yarrell's *British Fishes*, vol. ii. pp. 127, 128.

The only other British locality in which its historian mentions that this fish is to be found, is "the Hamble, which runs into Southampton-water;" but, as he very justly believes, this is owing, "rather to the want of a particular mode of fishing, by which so small a fish can be taken so near the surface, than to the absence of the fish itself; which, abounding as it

does in the Thames, I have very little doubt might be caught in some of the neighbouring rivers on our south and east coasts." This is certainly highly probable; and the same remark, doubtless, applies to other fishes which are usually said to be very local. We are, in general, very ignorant of the habits of fishes; and modes of fishing are the most local of all arts; so that in all cases in which there is any great similarity between one part of the water and another, it is always worth while to try, if what is got in the one could not be got in the other also, by using the same means.

The common whitebait net is small, only about three feet each way in the opening. It is put over the side of the boat, moved in a depth of from three to five fathoms, and let down to the depth of only about four feet. The fish come with the flood, but never ascend beyond the brackish water. This alone might have shown that they were not shads, as these often go many miles up the fresh. The heat produced by the mixing of the fresh and salt water is the stimulating cause which brings them, and also the reason why they move up and down with the tide. On this account they are not very likely to be found in all but tidal rivers, in which there is a considerable range of the tidal play.

Farther down the estuary of the Thames, whitebait are sometimes caught of larger size than on the grounds usually fished, and they are also caught nearer the bottom, and in deeper water; but while whitebait is the chief fish caught on the stations farther up, it arrives only as a straggler in those more seaward places; and, as is known to be the case with the pilchard, and supposed to be the case with the herring, it keeps more to the bottom as it gets farther out to sea. Whether it might not be followed into these localities, and taken by deeper nets than those now used; or rather, whether it might not be met as it returns from them, is a point worthy of investigation. We know, that in the case of salmon, the more seaward they are taken they are the better; but this may not hold in the case of white-bait, or, indeed, in that of any of the herring family. Herrings, themselves, are better when they are taken in the quiet bays, with fat bottoms, and the same may hold true of all the family. For salmon are fishes of colder latitudes, and hence they do not select the top of the brackish water, where the greatest heat is, for their spawning-places, but pass into the fresh of the rivers, and even, in some instances, hundreds of miles inland; although, as an article of food, their quality deteriorates from the moment that they quit the fully saturated water of the sea, or, at all events, the open sea water of the places to which they resort.

Whitebait, as is the case with the whole herring family, are very tender in their vital system; and, true to the general character of all animals which are thus tender, their flavour very speedily falls off, and they soon become putrid and unwholesome. They are so very delicate that they cannot even be carried to any great distance in boats which are provided with wells. They can therefore be had in perfection only in the immediate vicinity of the places in which they are caught, and the sooner they are dressed after being taken out of the water the better. This is an additional reason for ascertaining whether they may not be found in other rivers besides the Thames and the Hamble. In order to contribute our humble

mite to the ascertaining of this, we shall add a short description of the appearance of these very interesting little fishes; and it would be worse than affectation to attempt doing this in any other language than that of Mr. Yarrell.

"The length of the head," says Mr. Yarrell, "compared with that of the body alone, is as two to five; the depth of the body, compared with the whole length of the fish, as one to five; the dorsal-fin commences half-way between the point of the closed jaws and the ends of the short middle caudal rays; the longer ray of the dorsal-fin is as long as the base of the fin; the ventral-fin arises behind the commencement of the dorsal, and half-way between the point of the closed jaws and the end of the largest caudal rays; the tail long, and deeply forked. The fin-rays in number are—

"Dorsal, seventeen; pectoral, fifteen; ventral, nine; anal, fifteen; and caudal, twenty. The vertebrae of the spinal column are fifty-six.

"The head is elongated; the dorsal line less convex than that of the abdomen; the scales deciduous; the abdominal line strongly serrated from the pectoral fin to the anal aperture.

"The lower-jaw the largest, and smooth; the upper slightly crenated; the tongue with an elevated central ridge without any teeth; the eye large; the irides silvery; the upper part of the back pale greenish ash; all the lower parts, the cheeks, gill-covers, sides, and belly, silvery-white; dorsal and caudal fins coloured like the back; pectoral, ventral, and anal fins, white. The only food I could find in the stomach were the remains of minute crustacea."

This description, which is equally accurate and circumstantial, will enable any one who takes an interest in the seasonal fish of any of our rich tidal rivers to know this much-famed species, and if only one is found in a river, that will be sufficient to justify a fair trial with the whitebait net properly constructed and worked; for these fishes always come in shoals to their breeding-places, and very rarely straggle. From what Mr. Yarrell says of the food of this, the smallest and most delicate of the herring family, it is highly probable that the whole family feed upon those small crustacea and other little creatures which float in countless myriads in the sea, and are very much at the mercy of the currents, so that, according as those currents shift in their setting against each other the fishes which feed on the living load of the water may also require to shift. This may, in part at least, explain why the herrings are so apparently capricious on our eastern shores. Those shores have a current of tide from the north parallel to the general line of the coast, while, on the opposite coast of the continent, the tidal movement is in the reverse direction, or to the north, as far at least as the entrance of the Baltic. There is thus a general eddy and deposit of whatever is suspended in the middle of our eastern sea; and in the different estuaries and embayments along our east coast there are of course smaller eddies, which in like manner make their deposits, though to an inferior amount. The variable winds, and the action of the land-floods in the upper estuaries, must have considerable effect upon the eddy water which collects those little creatures that are taken up from their birth-place on the shores; and the removal of the food by this means, *en masse*, may co-operate with the consumption of

the fish in producing those periodical famines in some localities which drive the fish to others. But the free ocean, when once arrived at, is common to all; and the margin of the great central eddy, and of its banks, to which these fishes retire, are not subject to the same vicissitudes as the bays and estuaries. It is highly probable that there are also seasonal movements of great part of the food of these fishes, seaward at one time, and shoreward at another. No doubt many of even the very smallest crustacea carry their eggs attached to the under part of the body, and thus continue in the free water all the year without, in all probability, ever reaching the bottom. There are other creatures, however, upon which the herrings feed, which do deposit their eggs upon some substance, such as rocks, and more especially seaweed. There is a limit of depth, and want of solar action, beyond which no seaweed will grow, as is found by the bottom, which the deep sea lead always shows, being ruins, such as mud and broken shells; and we cannot suppose that any living creature will place its eggs beyond this limit of all vegetable action.

Even those small and floating crustacea that hatch their eggs on their own bodies, cannot so hatch them in the depths, but must come both near the surface and near the land, in order to enjoy the light and heat of the sun, the reflected and radiated heat of the bottom, and the stimulus of the atmospheric air. All these come to their maximum toward the end of summer, and thus the parent little creatures come shoreward at that time, and during the winter. At the same time the broods of the former year, having enjoyed the action of the sun and air near the shore during the summer season, begin to retreat in the winter; and thus, as these seasonal fishes approach the land, they are led by one part of their food, and they recede another.

The system is so beautifully contrived, too, that though all the productions of our seas are seasonal, their seasons are not all the same. Thus they come in succession to support each other, and with that surplus which is so very valuable to man, when he is industrious enough to avail himself of it. The subject is one upon which it is not easy to get accurate information, and it has been, for this reason, neglected. But still there is no subject in nature more interesting to a maritime people than the seasonal movements and actions of the sea, of which surface-fishes, and, above all, the herring family, are in a great measure the keys.

**HESPERANTHA** (Ker). A genus of Cape bulbs, belonging to the natural order *Irideæ*. They require the same treatment as the *Ixia*, &c.

**HESPERIIDÆ** (Swainson). A family of diurnal lepidopterous insects, or butterflies, distinguished by several remarkable characters. They are, for the most part, small dull-coloured butterflies, extremely active, flying with great velocity, but resting frequently upon leaves and twigs. Their hind tibiae are furnished with two pair of spurs, as in many moths, and the antennæ are short and clubbed at the extremity, have the tip bent into an acute hook; when at rest, the lower wings are elevated, the upper pair being extended horizontally. The spiral tongue is as long as the entire body, which is very robust. The caterpillars, of which a few only are known, are longated, naked, with a large head and sixteen legs.

When full fed, they fold the adjacent leaves together with the help of silken threads, within which they become chrysalides, which are not angular like the majority of butterflies, but short and smooth with a slender transverse thread. By English collectors, these butterflies are termed skippers, from their short and irregular jerking kind of flight. These butterflies, which were called by Linnæus, *Papiliones Plebeiæ urbicolæ*, were formed by Fabricius into the genus *Hesperia*, from which several others were subsequently detached. We have been surprised to observe that, in Mr. Duncan's recent work upon British Butterflies, these insects have been, for some unexplained reason, entirely omitted. We presume that this is an oversight, for the author will scarcely venture to assert that they are not butterflies, although, in some of their characters, they approach the moths.

The British species, (of which there are ten recorded, some, however, being doubtful natives,) were introduced by Fabricius into his genera *Thymele*, having the antennæ terminated in a curved club with an acute hook at the top, (comprising *Hesperia Alveolus*, and *Tages*;) and *Pamphila*, having the club of the antennæ straight and terminated by an acute hook, containing *Hesperia Paniscus*, *Linea*, *Sylvanus*, *Comma*, and some others.

The exotic species are very numerous, being mostly of a brown or dusky colour, with paler, white or talc-like spots on the upper wings; some of them are furnished with long tails to the posterior wings.

**HESSIAN FLY**. A minute dipterous insect, exceedingly destructive to wheat in America, belonging to the genus *CECIDOMYIA*, which see for an account of its ravages and figure of the insect.

**HETEROCERIDÆ** (MacLeay). A small but interesting family of coleopterous insects belonging to the section *Pentamera*, and subsection *Philhydra*; the body is small and oval but depressed, the antennæ with the seven terminal joints forming a serrated mass, the tibiae flat and spined, and the tarsi four-jointed only. The species are found in moist situations, preferring the muddy banks of standing water, in which they burrow by means of their tibiae, which are adapted to that purpose. There is one genus in the family, *Heterocerus* (Boëc), in which there are six British species.

**HETEROGYNA** (Latreille). A subsection of aculeate hymenopterous insects, distinguished, as the name implies, by the diversity in appearance of the female from the ordinary type of the order. Latreille introduces into this subsection the family of the ants (*Formicidæ*), which are gregarious, and in which the neuters or abortive females are wingless; and the family *Mutillidæ*, in which there are only two distinct sexes, the females being wingless. This sex is generally destitute of ocelli; the antennæ in all the species are elbowed, and the tongue is small, rounded, or spoon-shaped. Notwithstanding the diversity occasioned by the apterous condition of the females, it appears to us that the *Mutillidæ* are in nowise related to the ants, and that they are closely allied to the fossorial sand wasps, which they closely resemble in their habits.

**HETEROMERA** (Latreille). A section of coleopterous insects of great extent, of which the investigation is very difficult, but which are distinguished by having only four joints on the posterior tarsi, whilst the four anterior tarsi are five-jointed. Latreille divides the section into four subsections.

1. The *Melasoma*, having the elytra hard, claws simple, maxillæ with a hook, wings generally wanting. Families *Pimelidæ*, *Blapsidæ*, *Tenebrionidæ*.
2. The *Taxicornes*, having the elytra hard, claws simple, maxillæ without a hook, wings present, antennæ perfoliated or clavate. Families, *Diaperidæ*, *Cossyphidæ*.
3. The *Stenelytra*, having the elytra hard, claws simple or toothed, wings present, antennæ simple. Families, *Helopidæ*, *Cistelidæ*, *Serropalpidae*, *Cedemeridæ*, and *Mycteridæ*.
4. The *Trachelides*. Elytra flexible, claws bifid, wings present, head inserted upon a neck. Typical genera, *Lagria*, *Pyrochroa*, *Mordella*, *Anthicus*, *Horia*, and *Meloe*.

**HETEROPTERIS** (Humboldt). A genus of climbing and shrubby plants, natives of tropical America, belonging to *Malpighiaceæ*. Some of them are handsome and easily propagated.

**HEUCHERA** (Linnæus). A genus of North American perennial herbs belonging to *Saxifrageæ*. They grow well in any light soil in the open borders.

**HEYNEA** (Roxburgh). Indian ornamental trees belonging to the *Meliaceæ*. They are in our stove collections, and are propagated by cuttings.

**HIBBERTIA** (Andrews). A genus of climbing evergreen and deciduous shrubs, natives of New Holland, named in honour of George Hibbert, Esq., a distinguished collector of plants. Class and order *Polyandria Trigynia*, and natural order *Dilleniaceæ*. Generic character: calyx of five persisting sepals; corolla of five petals; stamens seated below the germen, filaments filiform, bearing oblong anthers; styles three or five, diverging and bent; seed-vessels several united, membranaceous, one or two-seeded. These are rather showy plants, with yellow flowers, but evolving a disagreeable scent. They are extremely easy of culture in the greenhouse.

**HIBISCUS** (Linnæus). An extensive genus of arborescent, suffruticose, and herbaceous plants found in every quarter of the world. Among themselves, the *Hibiscii* assume so many forms that botanists have divided them into twelve sections. They have generally showy, some of them magnificent, flowers, and form an interesting group in the natural order *Malvaceæ*. Several species have been employed in medicine and domestic economy. The stems of almost the whole consist of strong and tough fibres, so that they have been manufactured into cords and whips, such especially as *H. cannabinus*, *arboreus*, *clypeatus*, and *mutabilis*. The leaves of the two former are also eatable, and those of *H. esculentus*, as well as its fruit, are esteemed as food in the Levant. The petals of *H. rosa sinensis* are astringent, and are employed by the Chinese to make a black dye for their hair and eyebrows, and a blacking for shoes. The aromatic seeds of *H. abelmoschus* have been much lauded as stomachics, and they are added as a cordial by the Arabians to their coffee. The mucilage procured from the root of *H. manihot* is used in Japan as size, and to give a proper consistence to paper. The whole are easy of propagation.

**HICKORY TREE** is the *Carya alba* of Nuttall, a genus of North American timber trees, formerly called *Juglans squamosa* of Poir.

**HIERACIUM** (Linnæus). An extensive genus of herbs, chiefly European, vulgarly known by the

name of hawkweed. They are chiefly perennials, and found every where in meadows and dry pastures. Their colour is yellow, and resemble the flowers of the dandelion, only more numerous and much smaller. A few of them, particularly the *H. fruticosum*, a half shrubby one from Madeira, is esteemed as a greenhouse plant, but the generality are mere weeds. They belong to the natural order *Compositæ*.

**HIMANTOPUS**—Stilt or Longshanks. A very singularly formed bird, arranged by Cuvier in the snipe section of long-billed wading birds, but which does not appear to range very correctly in this part of the system, at least if we are to consider the order in the ordinary acceptation of *Grallæ*, or wading birds. Cuvier's *Echassiers* is not indeed so objectionable as *Grallæ*, but it is only not objectionable because it is not definite, unless the subdivision lead us in some way to the haunts of the birds. Indeed the birds under consideration are so peculiar that it is not easy to say what should be their place in the arrangement.

The generic characters are: the bill long, slender, depressed in the basal part, but compressed toward the tip; the nasal channel, extending half the length of the bill, and the nostrils of a lineal shape and long; the legs very long, much more so in proportion to their length than in any other bird, and as disproportionately slender as they are long. It is from this that the bird is called *Himantopus*, which means "cord legs," the legs being feeble and flexible as well as long. The feet have three toes, all turned to the front, the outer and middle ones being united with a broad membrane at their bases, and the inner and middle ones by a very small membrane. It is not easy to point out the kind of surface for which such feet are best adapted; but the birds are most frequently seen in waste and sandy places near the banks of rivers and the shores of salt lakes. The wings are also remarkable for having the primary quills much longer than any of the others. There are at least two species, one of the eastern continent and the other of America.

**COMMON STILT** (*H. melanopterus*). Top of the head, back, and wings, black, with green reflections in the male only; tail dusky grey; and all the rest of the plumage white, except a few streaks of dusky grey on the hind part of the neck. The bill is about two inches and a half long, the head and neck four, the body four and a half, and the tail two. The legs, when stretched out, extend at least five inches beyond the tail; they are bare of feathers for two or three inches, and are of a pale red colour, as are also the irides. The wings are long and much pointed, and the bird is evidently well fitted for flight. The body of the bird is lightly and handsomely formed, and the colour of its neck is particularly graceful. As a British bird, the stilt is a very occasional straggler; and we are thus ignorant of its habits. On the continent it is much more common, and therefore its habits are better known, though even there it is a bird of desert places.

But though not very often seen near the habitations of man, it is a bird very generally distributed. On the eastern continent it is found as far to the north as the salt marshes in the south of Russia, and the confines of Siberia. It is particularly abundant about the shores of the Caspian Sea and the lake of Aral. It is by no means rare in India, not only about the

great salt marsh, the Runn of Cutch, but in the Decan. It is met with in Egypt, and probably along the margin of the desert to the Atlantic coast of Africa; and specimens have been sent from Brazil, differing very little from those that inhabit and breed in Europe. There is one circumstance connected with the differences of its appearance in different countries, which shows that it is more a bird of the warm latitudes, which have seasons of wet and drought, than of the temperate or the cold. In India it is much larger than in Europe, the length being at least six inches. Those which have been brought from Egypt and from Brazil, are also larger than the European; and even those from the south of Europe are larger than those from the north. We have already explained, in the article *HERON*, why any animal should be considered as most at home in that country where it is most fully developed; and the stilt furnishes a proof of what was there stated.

Stilt.

In all these localities it is a gregarious or social bird, occurring in flocks which, from the arid nature of the places which they inhabit, are rather discursive and often on the wing. In respect of food, it appears to be partial to miscellaneous vegetable matters, the larvæ of aquatic insects, and very small shells have been found in the stomachs of those that have been examined.

In all the west of Europe they are migrant birds, and though they are not uncommon in the north of France and the Netherlands, where they appear to arrive by the way of the Danube to the Rhine, they are by no means so common in that part of France which is most directly cut off from the range of eastern birds by the Alps. The few that have appeared in England have been only one at a time; and there is no account, or even probability, of their breeding in this country. They have, however, bred in the north of France; but their principal breeding-places in Europe are the marshes on the lower Danube and in the south of Russia, though at certain seasons of the year they appear in flocks about the salt lakes and salt marshes of Hungary. Their nests are understood to be in the closest herbage of the marshes; but though they flock they breed so obscurely that their habits at those times are little known. The nest is said, however, to be constructed very rudely of a

few withered stems and leaves, or other vegetable debris; the eggs being five or six in number, of a yellowish colour spotted with reddish brown, and about the size of those of a partridge.

**BLACK HEADED STILT** (*H. nigricollis*). This is an American species, differing in some particulars from that of the east, and as we have the advantage of Wilson's observation and description of it it is much better known than that species, of the existence of which naturalists have been so much longer aware.

The black headed stilt measures about fourteen inches from the tip of the bill to the extremity of the tail, and the extent of the wings is about twenty-eight inches; the bill is about three inches long, slightly curved upward, and tapers to a very fine point. The upper mandible is rounded on the culmen, the nostrils are in the form of slits, but open, and the whole bill is of a black colour; the front of the head, a streak under the eye, and a spot behind it, and also the whole of the under parts, are pure white, which is also the colour of the actual feathers of the back, the rump, and the wing-coverts, but these are concealed by the mantle of long feathers issuing from the scapulars; a streak in front of the eye, the ear-coverts, the back of the head, the back-neck, the long feathers on the scapulars, and the quills of the wings, are deep black with rich reflections of green; the tail is square at the end, or very slightly forked, and the under coverts extend as far as the feathers; the legs are of a fine pale carmine red, the tarsi four inches and a half long, and the tibiae naked for a considerable distance above the tarsal joints; they are remarkably slender, and can bear to be bent to a considerable curve without injury; the feet are the same as in the eastern species; the wings are very long, extending beyond the tail nearly two inches, and they are very much pointed; there are some differences as to the distribution of white and black upon the neck; and the female, as is the case with the eastern species, is considerably smaller than the male. The stomach of this bird is a true gizzard, that is to say, it is very strong and muscular, though it appears to feed much more on shelled mollusca and coleopterous insects than upon vegetable substances.

Wilson appears not only to have examined it with greater care, but to have formed a more correct estimate of its place and occupation in nature than has been done by the naturalists of Europe; and as there is a very close resemblance between the two in every thing save colour, and not very much difference in that, we may consider the same observations as being applicable to both.

He considers it as coming nearer to the avoset than to any other bird; and if the two are carefully compared it will be found that while the avoset brings the series to the water from the soft billed birds, the snipes and godwits, the stilt brings it from the harder billed birds, the plovers and sandpipers. The avoset wades, and scoops the mud in the runs of water, finding its food by the touch of the bill more than by the sight of the eye; while, though the stilt is also a wader, it does not scoop the mud, or feed by the touch of the bill, but catches its prey by sight in the water, in the air over it, or on the aquatic plants. The length of the avoset's neck, as compared with that of its legs, points out that it is fitted for feeding

at the level on which it stands; but in the stilt, though the neck is long, and has a good deal of action, it is still so short in proportion to the legs, that the bird could not keep its balance, and reach with its bill the level on which it stands. Our common name stilt is therefore the most descriptive one that can be given to it; for it is really a bird "on stilts," that is, elevated for action above the plane of the feet.

This will give us at least a notion of the climates and localities for which the stilt is best fitted; and if we find these to accord with the actual ones in which it is observed, then we may safely conclude that we have found a clue to the use of the bird in nature, different as it is from those birds with which we are most familiar.

Now, the form of the legs in the stilt clearly shows that it is to wade in water, not beyond its depth of course, but still where its bill, long as it is, cannot reach the bottom; and though the slight turn upwards of the bill shows that the food is to be taken from a level below the common axis of the body, yet not so far below as in the case of the avoset. The legs of the avoset are also stout, to give it a firm base as it wades; whereas those of the stilt are very light and flexible. The foot too has the character of a swift foot, but the flexible leg does not answer to it upon land. The lightness of the foot, however, enables the bird to lift it in the water with very little exertion, and the flexibility of the tarsus makes it far less liable to injury from striking against obstacles in the water than if it had been a hard bone of the same weight. Thus, singular as this leg appears at first sight, when we come to examine the matter a little attentively we find that it is the very best foot for wading in shallow water,—in the same way as every thing in nature which our ignorance considers an imperfection becomes a perfection.

Such is the adaptation of the bird; and our next step is to find the places for which it is adapted. Shallow waters replete with living creatures are obviously the places; and wherever shallow water is exposed to powerful action of the sun, so as to have its temperature considerably increased, such water instantly becomes the stimulus to a vast number of living creatures; the larvæ of the larger water flies, water beetles, small crustacea, and univalve mollusca. The tropical countries, where they get flooded by the rains, furnish such places at one season of the year; and the shallow marshy pools of more temperate countries furnish the same during the summer; and it so happens that, in the northern hemisphere, which is the great hemisphere of seasonal migration, these alternate with each other. Thus we at once see that the stilt should be a migratory bird, and in what places it ought to be found. We have gone at some length into this subject, because the bird is a very singular one, and performs a very singular office in nature—a part peculiar to itself, as it were, in which it has no rival; and we have also done so because we believe there is no English work which gives any tolerable account of the economy of this bird, however correctly some may describe its appearance. As lawyers say, we have "taken the argument" upon the American species rather than the European one, because we can call Wilson as evidence; and if he bear out the case, we are sure of a verdict even from the most fastidious reader. We shall not mutilate the account given by the great ornithologist of America, though it is a little lengthy.

"This species arrives on the sea coast of New Jersey about the 25th of April, in small detached flocks of twenty or thirty together. These sometimes again sub-divide into lesser parties; but it rarely happens that a pair is found solitary, as, during the breeding season, they usually associate in small companies. On their first arrival, and, indeed, during the whole of their residence, they inhabit those particular parts of the salt marshes pretty high up towards the land, that are broken into numerous shallow pools, but are not usually overflowed by the tides during the summer. These pools or ponds are generally so shallow, that, with their long legs, the avosets can easily wade them in every direction; and as they abound with minute shell fish, and multitudes of aquatic insects and their larvæ, besides the eggs and spawn of others deposited in the soft mud below, these birds find here an abundant supply of food, and are almost continually seen wading about in such places, often up to the breast in water. In the vicinity of these bald places, as they are called, fifty yards off, among the thick tufts of grass, one of these small associations, consisting perhaps of six or eight pair, takes up its residence during the breeding season. About the first week in May, they begin to construct their nests, which are at first slightly formed of a small quantity of old grass scarcely sufficient to keep the eggs from the wet marsh. As they lay and sit, however, either dreading the rise of the tides, or for other purposes, the nest is increased in height with dry twigs of a shrub very common in the marshes, roots of the salt grass, sea-weed, and various other substances, the whole weighing between two or three pounds. This habit of adding materials to the nest after the female begins sitting, is common to almost all other birds that breed in the marshes. The eggs are four in number, of a dark yellowish clay colour, thickly marked with large blotches of black. Their nests are often placed within fifteen or twenty yards of each other; but the greatest harmony seems to prevail among the proprietors. While the females are sitting, the males are either wading through the ponds, or roaming over the adjoining marshes; but should a person make his appearance, the whole collect together in the air, flying with their long legs extended behind them, keeping up a continued yelping note of click, click, click. Their flight is steady, and not in short sudden jerks, like that of the plover. As they frequently alight on the bare marsh, they drop their wings, stand with their legs half bent, and trembling, as if unable to sustain the burden of their bodies. In this ridiculous posture, they will sometimes stand for several minutes, uttering a curring sound, while, from the corresponding quivering of their wings and long legs, they seem to balance themselves with great difficulty. This singular manoeuvre is, no doubt, intended to induce a belief that they may be easily caught, and so turn the attention of the person from the pursuit of their nests and young to themselves. The red-necked avoset practises the very same deception in the same ludicrous manner, and both alight indiscriminately on the ground, or in the water. Both will also occasionally swim for a few feet, when they chance, in wading, to lose their depth, as I have had several times an opportunity of observing. The name by which this bird is known on the sea coast is the stilt or tilt, or longshanks. They are but sparingly dispersed over the marshes, having, as has been already observed,

their particular favourite spots; while, in large intermediate tracts, there are few or none to be found. They occasionally visit the shore, wading about in the water, and in the mud, in search of food, which they scoop up very dexterously with their delicately-formed bills. On being wounded while in the water, they attempt to escape by diving, at which they are by no means expert. In autumn, their flesh is tender and well tasted. They seldom raise more than one brood in the season, and depart for the south early in September. As they are well known in Jamaica, it is probable some of them may winter in that and other of the West-India islands." The above is not only by far the best description of the manners of this genus of birds, but there are few descriptions of any living creature at all comparable with it.

**HIPPARCHIA** (Fabricius; SATYRUS, Latreille).

A very extensive genus of lepidopterous insects, belonging to the section *Diurna*, or butterflies, and family *Nymphalidæ*, having the antennæ gradually thickened to the tip, the club being slender and bent; the body is slender; the wings large; the palpi are longer than the head; several of the basal nerves of the wings are very much swollen at the base. The caterpillars are either naked or downy, with a forked tail; the chrysalides have the head forked, and the back tubercled. There are nearly a hundred European species of this genus, of which nearly twenty are inhabitants of this country, including the wood argus (*Ægeria*); the wall butterfly (*Megara*); the grayling (*Megara*); the marbled butterfly (*Galathea*); the gate keeper (*Tithonus*); meadow brown (*Janira*); the ringlet (*Hyperanthus*); and the small heath butterflies (*Pamphilus*); all of which are of common occurrence and of the middle size.

.. **HIPPOBOSCIDÆ** (Leach.) A family of dipterous insects, belonging to the section *Pupipara* (or order *Homaloptera*, Leach), containing the forest flies, which exhibit such remarkable variations in their typical structure, that they have been regarded by some authors as forming a distinct order. The head is received into a cavity in front of the thorax; it is divided transversely into two parts, the anterior or smaller of which supports the mouth and two small tubercles, almost imbedded at the lateral angles, being rudimental antennæ. The mouth is composed of two curved setæ, inclosed in a tubular canal, covered by two narrow elongated coriaceous plates, regarded by Latreille as palpi. The ocelli are wanting. The body is short, flat, and very coriaceous; the wings are either large or entirely wanting; the nervures of the anterior margin are very strong, but they are effaced behind. In the winged species a pair of balancers are also present. The legs are very strong, and terminated by robust curved claws, which are toothed beneath. The abdomen is composed of a continuous leathery-like membrane, capable of very great distension, which peculiarity is owing to the remarkable circumstance that the young of these insects are singly nourished within the body of the parent, where they not only acquire their full size, but actually assume the pupa state, under which form, like very large eggs, they are deposited by the females. This egg-like cocoon is at first soft and white, nearly as large as the abdomen of the parent fly; but by degrees it hardens, becomes brown, of a rounded form, and often notched at one end, which is covered by a shining kind of cap, which

is detached on the insects assuming the perfect state. This cocoon is, moreover, entirely destitute of annular incisions, in which respect it differs from those of other dipterous insects. It is composed of the uncast skin of the larva, beneath which the insect becomes a real inactive pupa, with the limbs of the perfect insect laid along the breast as in other species which undergo the strict coarctate species of transformation. These curious particulars were first discovered by Reaumur, and have been subsequently confirmed by M. Leon Dufour, and others; the former author was, indeed, so solicitous to observe the development of the insect from these singular eggs, as he at first supposed them, that he carried them in his pocket by day and took them to bed with him by night, in order that they might have the same warmth which they enjoy in their proper habitats. His surprise may therefore be imagined, when, instead of grubs, as he expected, perfect flies were produced.

These insects are not less interesting in respect to their habits: they live exclusively upon various quadrupeds and birds; the horse is especially subject to the attacks of one of these species, which has thence been named *H. equina*. This species is the type of the genus *Hippobosca*, in which the eyes are large and distinct, being placed at the sides of the head; the antennæ are in the shape of tubercles with three dorsal setæ; the wings are large. Mr. Curtis observes, that "these flies move swiftly and, like a crab, sideways or backwards; they are very tenacious of life, and live principally upon horses, attaching themselves to the belly, between the hind thighs and under the tail, where they are less protected by hair. It is remarked by Latreille, that the ass fears them the most, and that horses suffer very little from them, probably when they have overcome the irritation which they must at first occasion, they cannot cause much pain, otherwise horses could not live in forests in the summer." And Mr. Samouille states, that "in the New Forest of Hampshire, they abound in a most astonishing degree. I have obtained from the flanks of one horse six handfuls, which consisted of upwards of a hundred specimens. Mr. Bentley informs me, from observations he made in the summer of 1818, while in Hampshire, that the *Hippoboscæ* are found in considerably greater abundance on white and light coloured horses than those of a black and dark colour; and the observation was confirmed by the stable-keepers in the vicinity of the Forest."

The other genera are, *Ornithomyia*, *Craterina*, *Oxypterus*, *Hæmobora*, *Melophagus*, *Feronia*, *Lipopterna*, and probably *Braula*; of these, the three first are British, and are found upon various birds, the *Craterina hirundinis* depositing its egg-like cocoon in the nest of the swallow, where it receives all the necessary warmth, for which it repays the poor swallow by sucking its blood. The wings in this genus are very long and narrow. The genus *Melophagus* comprises a single species, *M. ovinus*, which is destitute of wings, and attacks the sheep. It is of a dark reddish colour, with the abdomen whitish. It is commonly called the sheep louse, and is so tenacious of life, that Ray states that it will exist in a fleece twelve months after it is shorn; its excrements even giving a tinge to the wool, which is very difficult to be discharged.

**HIPPOCASTANÆÆ.** A natural order containing only two genera, namely, *Æsculus*, the horse-chestnut, and *Pavia*, the scarlet-flowering chestnut. The different species of *Æsculus* and *Pavia* are

commonly known under the name of horse-chestnuts, reference being obviously made to the external resemblance the fruit bears to that of the *Castanea*, and the very bitter astringent taste, which renders it unfit for human food. The seeds are large, and abound in farinaceous matter; hence they are very nutritious, and some animals devour them greedily, especially after the nuts are steeped in lime water. If allowed to germinate they become sweeter, and then are relished by rabbits and pigs. The bark of the horse-chestnut is bitter and astringent, and has long been esteemed as a febrifuge. This tree, though very common in this country now, was unknown in Europe three centuries ago. Parkinson says "our christian world had first the knowledge of it from Constantinople," and, as an evidence of its rarity, Clusius states, that there was only one tree of it at Vienna in his time. The horse-chestnut is one of our finest flowering trees, and on this account is frequent in park scenery.

Some of the *pavias* bear beautiful scarlet flowers, and, as ornamental trees, will be very generally planted. The timber of neither is durable, and only used by turners. The horse-chestnut is readily raised from seeds, and the *pavias* are increased by grafting on the former.

**HIPPOCRATEA** (Linnæus). A genus of climbing plants, natives of the East and West Indies. They belong to the third class and first order of Linnæus, and to a natural order, to which they give a title, namely,—

**HIPPOCRATEACEÆ**. This is a small natural order of plants, comprising five or six genera, being climbing shrubs, or trees, with in general smooth stems, opposite, simple, somewhat leathery leaves, entire or toothed, and furnished with small deciduous stipules. The inflorescence is axillary, paniculate, or in bundles, and the flowers small, regular and united. The *Tonsella*, one of the genera, are said to bear poisonous fruit. Such of the genera as have been introduced into British collections are propagated by cuttings.

**HIPPOCREPIS** (Linnæus). A genus of annual herbs, and trailing or shrubby perennials, one of them is a native of England, and called the horse-shoe vetch from the resemblance of its crooked pods. They belong to the natural order *Leguminosæ*, are sometimes seen in flower borders, and raised from seeds, which ripen plentifully.

**HIPPOMANE** (Linnæus). *H. mancinella* is the Manchineel. A lofty tree, native of the West Indies, so called from its effects on horses which eat of it. The flowers are monœcious, and it belongs to the order *Euphorbiaceæ*. The hippomane is certainly a dangerous plant; but the poisonous properties of it have been very much exaggerated. The timber is beautifully veined with brown and white, and capable of receiving a high polish; but before the trees are felled, fires are usually lighted round them, to inspissate the sap, and render the feller's occupation less dangerous; for, even when the juices are not applied to produce death, they cause intense pain, likened to the burning of a red-hot iron. The plant is kept in our stoves, and grown in sand and moor earth, and is easily propagated by cuttings.

**HIPPOPOTAMUS**. A remarkable genus of pachydermatous mammalia, of which there is only one living species known, inhabiting the larger rivers of Africa and their margins, and feeding on the strong and coarse aquatic plants. The elephant and the rhinoceros, among animals of this class,

bring us to the very margin of the water, though it must be a margin where there is a strong coat of vegetation to support the steps of such heavy animals. The hippopotamus follows these two, and brings us actually into the water, in which the animal chiefly resides during the day, often with nothing but the nostrils above the surface. We shall, perhaps, find a future opportunity of showing that the pachydermata, as they remain now, are the fragments of an animal population which was once far more numerous, more widely distributed, and more characteristic of the earth than it is now; but we may in the mean time remark, that pachydermatous animals are the only large mammalia found native on some of the more remote isles of the Pacific.

The name *Hippopotamus*, or "river horse," which has, from the earliest times been given to this animal, occasioned many mistakes on the part of the elder naturalists with regard to its appearance and character; but as the animal is now well known, it is not necessary to advert to these mistakes of the darker ages.

The generic characters are: four toes on all the feet enclosed in little hoofs at their extremities, six cheek teeth on each side of both jaws, the first three of which, toward the front, are conical, and the three posterior ones furnished with two rows of points on the crowns, which, in time, wear down into a sort of trefoil form. There are four incisors in each jaw: the upper ones short and conical, bent inwards towards the mouth; the under ones long, cylindrical, and pointing forwards. Canines in both jaws, the upper ones nearly straight, and the lower crooked; the two acting strongly against each other.

The body is heavy and massive, the legs very short, and the belly almost in contact with the ground. The head very large, more so in proportion even to the large body than the head of any other mammalia; but this size arises from the great production of the bones of the mouth and those that afford insertion to the muscles which move the jaw, and not to any superior development of the cranial cavity, which, on the other hand, is comparatively small. The muzzle is large and thick, so as to cover the powerful armature of the mouth. The tail is short, the eyes and ears small, the coat without fur, and of a dark and repulsive colour. The whole aspect of the hippopotamus is repulsive. It has a very stupid look, and yet its air is ferocious; and its mouth, though not in any respect of a carnivorous character, is about as ugly a mouth as can well be imagined.

Still the hippopotamus is by no means destitute of interest, and that interest is heightened when we reflect that, as a species, it stands alone in its genus, and occupies a place in nature which could be filled by no other existing animal. On land it is a very awkward walker, not only on account of the shortness of its legs, but because its body is specifically heavier or understood to be so, than most other animals. This probably enables it to keep its footing in the water much better than if its specific gravity were more nearly the same. Its usual motion in the water is not swimming, but walking, though it can swim, as indeed most of the Pachydermata can readily do. It frequents the muddy banks of the rivers, usually where the vegetation is rank, is seldom out of the water during the day, but comes to the land to feed during the night. Though dull as well as ferocious in its disposition, it is very timid on land, as if it felt

itself not at home there; for upon the least noise being made, or alarm given, it takes to the water, plunges to the bottom, and only raises the nose above the surface occasionally for the purpose of breathing. When it plunges into the water, it makes a great splash, and the flood covers its descent with foam and rippling. It also can expire the air which it has in its lungs when under the water; and this causes that bubbling of the water to which allusion is made in the account of *Behemoth* in the Book of Job, which, no doubt, alludes to the hippopotamus, as the *Leviathan* is, in all probability, the crocodile of the Nile. The best authorities (for it is a question of authorities) ascribe the Book of Job to Moses; and from his education in Egypt, the crocodile and the hippopotamus must have been the aquatic animals with which he was best acquainted. *Behemoth* appears to have had, among the Hebrews, the same meaning as "brute" has with us; that is, a heavy animal feeding upon vegetable matter; and "behemoth" is usually translated "cattle," in distinction to the more general word "beast," although the use of that as a general term is improper. "*Behemoth* on a thousand hills," is the expression which, in the common version of the Bible, is rendered "the cattle on a thousand hills." Now there is no inhabitant of the waters to which such an epithet can be properly applied, but the hippopotamus; and it is remarkable with what truth the characters of the animal are marked by the inspired writer.

It is probable that, in the days of Moses, these animals abounded in the Nile throughout Egypt; for mention is made of them in the streams of the Delta at a more recent period of history. Now, however, they are not found in Lower Egypt, nor in any part of the Nile below the cataracts. They do occur in the upper parts of the river, though probably not in such numbers as they did in former times. Burkhart says, "The hippopotamus is very common in Dongola. It is a fearful plague there on account of its voracity, and the want of means in the inhabitants to destroy it. It often descends the Nile as far as Sukkat. In 1812, several of them passed the Bahr el Hujjar, and made their appearance at Wadi Halfa and Dan; an occurrence unknown to the oldest inhabitants. One was killed by an Arab by a shot over the eye. The country people ate the flesh, and the skin and teeth were sold to a merchant of Sioutt. Another continued its career northward, and was seen beyond the cataract of Assauan at Deran, one day's march north of that place." Their descents to the north are, however, of rare occurrence; and the hippopotamus must now be considered as an animal of the central and southern parts of Africa only.

Above the cataracts of the Nile, where the country becomes broader and more fertile, these animals are much more abundant. In Senaar they inhabit both branches of the river, and in their nightly excursions on shore they are very destructive to the crops, not only eating great quantities, but trampling down the rest with their large and clumsy feet.

They are long animals, not less than ten or eleven feet from the nose to the tail; but they do not stand higher than between four and five feet. Their steps, also, are very short, so that they make an absolute rut in passing over soft ground. The quantity which they eat is enormous, much greater than that eaten by any other known animals. The stomach can contain five or six bushels, and the large intestine is at least eight inches in diameter. It is not without

reason, therefore, that the people dread their visits. It is true that their digestive powers are not great, or rather, perhaps, that their ordinary food contains but little matter fit for their nourishment. Their mouths are adapted for tearing and dividing hard and tough plants, but not for grinding any substance to a pulp, as is done by ruminating animals. Half their cheek teeth are, as we have said, conical and pointed, so as not to be in any way grinding teeth, and the remaining ones are also but ill fitted for such a purpose. Besides, though they have a compressing motion of the jaws which is very powerful, they have no lateral or grinding motion, and all that their mouth can do to the food is to bruise it a little. Thus the stomach does not dissolve any of the ligneous or harder part of the food, but merely extracts a portion of the juice, so that the great mass of the food passes off in a state comparatively little changed. As compared with most other animals, there is but a small portion of what is taken into the mouth that goes to the nourishment of the body; and thus the animals may be said to be always burdened with the refuse of what they swallow. Most of the pachydermata have the functions of digestion less perfect than those of other herbivorous animals; and if it is of very hard consistency, they only draw a tincture from it. This is the case with the horse, which, although like the hippopotamus, wholly a vegetable feeder, differs the most from it in many respects of any animal in the class. The hog, which is more omnivorous, does the same, at least when it does not get food which is succulent, and then it fattens more than any other animal. In England, where horses are much fed upon dry food, there still remains so much substance in it, that the grains which they drop on the roads serve for food to a vast number of birds.

As the hippopotamus appears to feed upon more coarse and rough substances than any of the order, not excepting the elephant and the rhinoceros, neither of which has the teeth at all fitted for tearing substances of the same toughness. The very peculiar teeth of the elephant, if we except the tusks, which do not in any way act in the taking or preparing of the food; the teeth are all grinders, or rather bruisers; and although the rhinoceros has two cutting teeth of considerable size and strength in each jaw, yet the majority are bruising teeth. Neither of those animals could therefore subsist on the same kind of food as the hippopotamus; and not taking their food into the stomach in so rude a state, or of a nature containing so little nutriment, they do not require it in such vast quantities in proportion to their bulk.

This very peculiar mode of feeding fits the hippopotamus for the very rudest life of all the mammalia. Its office is to clear the rivers of those vegetable remains which, if allowed to accumulate in countries where vegetation is rapid, and the rains fall heavily in their seasons, would choke up all the passages, and turn all the flat lands into at least periodical marshes; and in order to fit them for this very laborious service, they are exempted from some of those labours to which other animals are subjected. When in the water they are supported on all sides by the pressure of that fluid, so that the weight remaining to press on the feet is small, as compared with that of the whale; and there is also much less waste of the body of an animal that keeps the water, than of one exposed to the air. Besides, they are not so much infested by those insects which are near the water, and which

give so much annoyance to many mammalia, as if they were in the free air, though, like the other pachydermata, they wallow in the mud. These considerations may help us in forming a guess at what may have been the condition of the globe when hippopotami were much more numerous than they are now; for though there are adaptations to climate in the external covering which have nothing to do with the internal anatomy of animals, yet when we find a skeleton of a definite type, and know the living animal to which it answers, we can always make pretty sure of the food and manner of feeding of the species of which we actually know only the bones.

The hippopotamus is found in the rivers of Western Africa, and also in the larger ones near the Cape, but it has been rarely seen in the former of these localities, though much more frequently in the latter. It is not found near the sea in any place so much as in the interior, and those places which have strong vegetation, and where the banks are liable to seasonal overflow by the water. These are the places in which its peculiar services are most wanted, because they are the places where the water-courses are most liable to be choked up by vegetable remains. Those places which are the favourite haunts of the hippopotamus are also the favourite haunts of the crocodile; and on the banks of the Upper Nile, while the one tramples down and eats the crops, the other often carries off the people. Lord Prudhoe, who travelled in Sennaar in 1829, mentions numerous instances of depredations by these formidable reptiles. He did not see any one carried off, but places were pointed out at which such things had occurred only a few days before. In one of those instances a crocodile snatched up a man who was washing clothes on the bank of the river, and instantly made for the opposite side with its prey; but, in the passage, another crocodile saw the prize, and followed the first, when a fierce battle ensued between them. Though crocodiles usually feed on the land, they fight better in the water, and so they plunged into the river to finish their combat in due form. In the meantime, the dead body of the man—drowned, not bitten, to death, which is the habit of crocodiles—was removed and buried, so that the reptiles had only their fight for their pains.

But though the crocodiles are thus formidable to man on the great rivers of the interior of Africa, it does not appear that they offer the least annoyance to the hippopotamus. That animal is truly the monarch of the wild flood. Neither lion, nor any other carnivorous beast, attacks it. This is not on account of the thickness of the skin; for, though the skin is about half an inch in thickness, and stiff, it is not hard, or destitute of sense of pain.

The skins of the Pachydermata are almost all very sensitive to the attacks of insects; but for even a lion to spring upon a hippopotamus would be rather a perilous matter, as the animal would instantly plunge, dive, and drown the lion. On the other hand, the crocodile could not make much of the hippopotamus. In the first place, no crocodile could carry off so large an animal; and, in the second place, the mouth and bite of the hippopotamus are by far the most formidable of the two; and though, in its natural habits, the hippopotamus bites only vegetable substances, yet it would of course bite an animal in self-defence; and, from the size, the form, and the hardness of the teeth, and the great force with which they can be made to act, there is little doubt that its bite would

be more formidable than even that of a lion. Its mouth is not, to be sure, a killing one, but, if applied to an animal, it would mangle dreadfully. Thus, while this savage and powerful, though dull and sluggish animal, lives at comparative peace, on its own part, with the whole of animated nature, it is perfectly indifferent to all that are around it.

Still these animals are not without their battles; for it seems to be a very general law of nature, and for aught we know, it may have its physiological use in keeping up their energy, that, in all the more powerful animals which are vegetable feeders, the males fight desperate battles of gallantry. Horses, bulls, rams, and many others, are terrible in their amatory wars, while even the most savage of the carnivora rarely fight upon this account. The same holds good in the case of birds; and we believe that the pugnacious beetles, which are engaged with each other as a gambling sport in some parts of the east, are vegetable feeders. We are sometimes apt to attribute these excitements wholly to the heat of the sun and the season; but the fact of such battles taking place among the hippopotami, which are constantly bathing in the cold flood, shows that there is something in the nature of the animal, and that the propensity is stronger in proportion as the animal is more vegetable in its feeding.

When lying on the bank of a river, the hippopotamus seems a vast and shapeless lump, and one would hardly take it to be an animal. The eyes are small, even if open; the ears are also small; and though the legs and tail are very stout, they are short. There is also a want of muscular marking on the body, for, if the animal is at all in good condition, there is always a thick layer of fat over it. This fat in the recent state, and when the animal is obtained from the water, is of some consistency; but it contains less stearine than even the fat of the hog, and thus soon passes into oil, and becomes rancid from the putrefaction of the cellular substance with which it is mixed, when it is exposed to the warm air, and especially to the direct action of the sun. The Dutch inhabitants of Southern Africa, who call the hippopotamus the *zee-coe*, or "sea cow" (though it is never found in the sea), are very fond of this fat, which they call *spek*, the name given to the fat of the whale, and also to that of the hog; and when they succeed in killing the animal, they preserve this fat by salting it, usually allowing all the fat which they cannot remove to drain from the muscles as oil, and drying these in the sun, as a harsh, but not unwholesome food. The greater number of the Pachydermata have a tendency to accumulate soft fat or lard under the skin, and this tendency is always the greater in proportion as the animals are more aquatic in their habits. In this respect the hippopotamus exceeds all the rest, making the nearest approach to the *Cetacea* of any footed animal, and hence we find in it the greatest tendency to the accumulation of this kind of fat. There is no doubt that it answers the same purpose in all these animals. An aquatic habit, or even a habit of wallowing much in the mire and sludge of rivers, is inconsistent with the possession of a thick furry coat, by which the animals could be protected from changes of temperature; and the substitute for this is the coat of fat under the skin, fat being, like fur, a bad conductor of heat. The transition from the water to the air, on the part of the hippopotamus, is almost as great a change in tempera-

ture as the instant change from midsummer to midwinter would be in our latitudes, and thus the animal requires a natural protection against it, so that the muscles, and especially the vital organs, may not be subjected to violent shocks.

It is true that the hippopotamus seldom comes to the land, or even to the surface of the water, during the day, but still the night air in such places is much warmer than the water. Fat, when melted, does not resist the passage of the action of heat so much as when it is not, and the readiness with which the fat of this animal melts in the sun may be one of the causes which keeps it in the water during the day; for, when the fat of a living animal passes into oil on or in its body, the consequences are very serious, as the cellular tissue in which the fat is enclosed soon putrefies, and spreads corruption through the system. The colour of the skin, which, though it varies a good deal in different individuals, is generally of a dingy bluish black, also tends to keep these animals under water during the heat of the day. This colour is one which rapidly absorbs the heat; and it is worthy of remark, that this is the prevailing colour of the upper part of almost all those mammalia which inhabit the waters, and in this uniformity of colour we must presume that there is a uniformity of use. From this habit of keeping the principal part of the body under water during the day, which appears to be a necessary result of the structure of the hippopotamus, it is rarely seen, and comparatively little is known of it in proportion to its numbers. We cannot positively state even what is the style and rate of its march upon land; and we say that it must be slow, rather from our judgment of the power of the animal, than from the fact as actually observed. For the same reason we know little of its habits when breeding, or whether the males are polygamous or not. The circumstance of their fighting would lead us to conclude that they are polygamous, but still the conclusion is only a conjectural one. For similar reasons the animal is seldom shot, unless by very expert marksmen. Large as it is, it offers but a small mark to the sportsman; for, in general, the nose, the eyes, and the ears, are the only parts above the surface, and these are all so near the plane of the face, that that is very little elevated. A bullet, unless it happens to hit very obliquely, will readily penetrate the skin at any part; but it is difficult to get any aim except an oblique one at the visible part; and if the part under the water is aimed at, the bullet is very apt to glance.

When only the face of the animal is above the water, the straight outline and erect ears give it some resemblance to the face of a horse, that is in the general contour. This may have been the reason why it at first got the name of the river-horse; but a very small portion more of the animal appearing destroys all similarity. The "sea-cow" of the boors of Southern Africa is still worse, for it has no connection whatever with any of the ruminant animals. Some have proposed to call it a hog; but although that is one step nearer than the horse, it also gives a false notion of the animal, because it has none of the habits, and very little of the appearance of a pig.

Wherever the hippopotamus is seen attempts are made to kill it, if the people are in possession of any arms fit for the purpose. This is done in cultivated districts, chiefly on account of the mischief that it does; but the flesh, the skin, and the teeth are all of

some value. We have already mentioned its use as food. The skin is not of much use as leather, and in cold climates it gets hard and brittle; but the skins of those that are killed in the Nile are made into a kind of whips, which are held in considerable estimation in that country. For this purpose the recent skin is cut into triangular stripes, about five or six feet long, pointed at the one extremity, and gradually increasing in breadth till, at the other extremity, the breadth is equal to the circumference of the intended whip at the thick end. The stripe is then rolled into a conical pipe, tied firmly together, and dried in the sun, after which it keeps its shape, and is light, dry, and elastic. The teeth, that is the large canines, are more remarkable for the compactness of their bone or ivory, and the hardness and beauty of them, than the teeth of almost any other animals. They are not teeth growing from roots, but tusks placed on cores, and hollow for about half their length, like the tusks of elephants. As is the case with all tusks which grow in this manner, such as those of the elephant and the morse, the substance of them is ivory, but it is ivory of very fine grain and remarkably hard and tough. The enamel, of which there is hardly a trace in the tusks of the elephant, is very thick, and so hard that it strikes fire with steel. They are in fact the strongest of all known animal substances: they are very much sought after by dentists for making artificial teeth, and when a piece can be had of such a form as that the teeth can be worked in the enamel, they preserve their colour almost as well as the natural teeth. On this account the tooth sells for about a guinea and a half a pound, though half the tooth is unfit for the dentist's purpose; and from its great solidity it is very heavy in proportion to its bulk. The teeth of the mouse come nearest to these, but they are very inferior.

The female hippopotamus is said to go nine months with young, though the fact has not been ascertained with precision; and the young are very soon able to take the water, in which the females are well able to defend them from enemies.

Though this singular genus of animals is now reduced to one species, and that existing merely as a fragment in one part of the world, and obviously upon the decline, yet the remains which are met with in the earth show that it has once been a general and characteristic inhabitant of at least all the temperate parts of the eastern continent. Of the middle of Asia, indeed, we cannot say much; first, because that remote and extensive country is now a desert, and, secondly, because it appears to be the native locality of the horse, which is the least aquatic of all the Pachydermata. In Europe there are, however, the remains of not fewer than four species, varying so much in size that we may suppose them to have been adapted for rivers of all magnitudes, from the wide sweeping flood to the small brook; and these are not confined to one locality, but found in Italy, in Germany, in France, and in England. That they have not been met with in other places, where the geological character of the country indicates that the animals could have resided, arises more from the want of observation than from any thing else. The observation is no doubt a matter of great difficulty, for no human industry can search the ten thousandth part of the matter deposited even in one extensive valley; then what can be hoped in the case of what have obviously been the general sepulchres of nature for thousands of years.

Hippopotamus.

The great fossil hippopotamus has been found in the clay deposits of many countries, as, for instance, in the valley of the Arno in Italy, in the south of France, near Paris, at Kirkdale in Yorkshire, and at Brentford, in the valley of the Thames, so that it must have been a very general inhabitant of Europe; and Europe must then, in the characters of its waters, have resembled what Africa is now, in those places where the hippopotamus is found in the living state.

Climate, at least so far as depends upon temperature, does not form any necessary or important part of this great question; for as we have the actual fact of an elephant having existed in the extreme north, with a covering better fitted for protecting it from snow and cold than that of any animal now living, while in its anatomy, and therefore by inference in its mode of life, it did not differ much from the elephant, as now found in Asia and Africa, we have no reason to doubt that the other large pachydermata of the north, which are also extinct, were equally adapted to a climate even more rigorous than that of the places where their bones are found at the present day. There are some indications in the form of the fossil skeletons, especially in the parts fitted for motion, which would lead us to suppose that those hippopotami of ancient days were more active than their congeners of the present time. There is more strength in the heads of the bones, as well as more length; and both of these indicate that the muscles were more powerful; the teeth are also stronger, and there are some differences in the cranial bone, which perhaps warrant us in concluding that the animals had more resources.

What the state of the earth was when the hippopotamus was common in Europe, we cannot tell, and shall never, in all probability, arrive at in a satisfactory manner. But we have no reason to believe that the axis of the earth's rotation had a different position from what it has at present; and though the obliquity of its orbit varies, the variation is slow, and is understood to act on their limits, or to involve in itself the means of a return to the same angle after a very long period of years. Hence we cannot suppose that the seasonal action of the sun was very different then from what it is now; for the notion, which has been at different times altered of the stroke of a comet, or some such imaginary cause, tilting the axis of the earth from the perpendicular, is not only gratuitous, but absurd. We have no reason to believe that the earth would be very much affected by a comet, even though it were to pass through one, as the satellites of Jupiter were not in the least disturbed by a comet which got within their sphere of action. Besides, the motion of the earth on its axis is not in any way affected by any body in the heavens, or by any known quality or circumstance of the earth itself. We can see no reason why it should be different now from what it was at the moment of the earth's creation, or why it should become different at any future time of the earth's duration, even if all the rest of the solar system were destroyed, and the earth stood still in its orbit.

In contemplating our own country and latitude as being inhabited by these great pachydermata, which are now found only in the southern parts of the old continent, we must therefore assume, that the annual action of the sun upon the earth must have been nearly the same as it is now. That the earth in our latitudes must have been more humid, and covered with a ranker and ruder vegetation in the

days of those pachydermata than it is now is perfectly obvious; inasmuch as such animals are found only in places where there is a rank vegetation. Water and vegetables are much less affected by changes of temperature than the solid and inorganic parts of the earth, and therefore we may presume that, in these former times, there was much greater uniformity of the seasons—a different vegetation certainly, but one which underwent less marked seasonal changes. The true ferns, and other plants analogous in many of their characters to those that are now met with only in the warm latitudes, prove this. But the very same circumstances must have tended to prevent that drain of heat from the polar latitudes to the equatorial ones which certainly now takes place; for much of the action of the sun goes off to the atmosphere by radiation, and as the air on the surface upon which this radiation of heat chiefly tells, is always creeping toward the equator, it must follow that the cold latitudes are cooled by this means, and that they are more cooled in proportion as the equatorial parts are more converted into desert. This inquiry is a most tempting one, and if we pay even the very slightest attention to these remains of the old world which we meet with at every step, we can hardly avoid entering upon it; but the links in the chain of evidence are so broken that, in the meantime, it is little else than a pleasing dream. The labour of many hands, and the wisdom of many heads, will still be required before the subject is so well explained as to bring it within the limits of popular science.

The middle-sized hippopotamus is the next of the fossil species in point of size, and it, as well as the smaller ones, seems to be wholly extinct, nor have any vestiges of it been found in those parts of the world which the living hippopotamus inhabits. This species, of which the remains have, we believe, been hitherto found in France only, seems to have been about the size of the common hog, and as this is found in the calcareous tufa, which, though a fresh water formation, is in all probability older than the debris in which the remains of the larger one are found, we may perhaps conclude that it became extinct at an earlier period of the earth's history. Only mutilated fragments of the skeleton of this animal have been found; but still there are enough to show that it was a hippopotamus, though different in some respects both from the larger fossil one, and from that which still exists in the living state.

The small fossil hippopotamus has been found in greater abundance than the last species. It has been found in the lower valley of the Garonne, and the flats between the estuary of that river and the Pyrenees, in accumulations of bones at Gibraltar (the whole rock there is, in fact, curious in this respect), in Dalmatia, and in some other places. It is less than the common hog; and the worn state of the teeth shows that it is not the young of any animal. The tusks are crooked, rather more so perhaps than in the living rhinoceros; but still their shape and curvature are quite different from those of any species of hog; the jaws are rather larger, and the muzzle not so broad as in the living species. What effect these differences may have had in modifying the habits of the animal, we are unable to tell; but the general structure clearly shows that it belongs to the hippopotami genus.

The least fossil hippopotamus is less than either of the former. The remains indicate an animal about the

same size as that small and very short-legged variety of the common hog, which was first introduced into Europe from the east of Asia, and is usually called the Chinese breed, though we believe it came at first from countries more southerly than China. The remains of this species have hitherto been found in France only, but we have no reason to suppose that they were confined to that country, only it so happens that the animal remains of France have been examined with more attention than those of most other countries.

Such is a slight notice of all the leading points that are known respecting one of the most singular genera in the whole class of mammalia. They are animals highly interesting in themselves from their very singular mode of life, the powerful manner in which they are armed, and the labours which they perform in the general system and economy of nature. But to those who wish to study the progressive history of the world, and read in a known language those wonderful memorials of former times which are buried in so many places of the earth, they are of still greater importance. We find the living hippopotamus more confined in the range of its pasture, and thus more exclusively fitted for that pasture, than any other animal; and when we examine what that pasture is, we are in so far enabled to judge of what must have been the state of the world when the hippopotamus was a more general inhabitant.

**HIRTELLA** (Widenow). A genus of West India trees, so called, from the extreme hairiness of the young shoots. The flowers are pentandrous, and belong to the natural order *Chrysobalanææ*.

**HIRUNDO** (Swallow, or *Hirudinidæ*, the Swallow tribe). A well defined family of birds, belonging to Cuvier's *fissirostral* sub-order of *Passeres*. Several of the species are well known to every body from their familiarity in coming close to human dwellings, their labour in the building of their nests, and their rapid and graceful motions on the wing. In temperate latitudes they are all migrants, marking the beginning of the summer by their coming, and giving notice that it is over by their departure. On these excursions they are generally very true to the season; but a stray one is sometimes tempted to visit the warmer latitudes before our spring storms, and suffers for its temerity. Hence the proverb, "One swallow makes no summer," which means that we ought not to found strong hopes upon slender foundations.

Some of the family find the principal part of their food over the surface of the water, for the greater part of the time that they are in their northern or summer haunts; and all of them resort to the surface of the water when they arrive, and most collect in flocks near the waters before they depart. When natural history was but little understood, the reasons of this were not seen, and consequently erroneous ones were alleged. This is one very remarkable instance of the effect of neglecting a caution which we ought never to forget when we reason beyond the facts on the habits of animals, or indeed on any thing connected with the active economy of nature. There is but *one truth* in every case, and *all else* that can be alleged is error, the proportion between which is every possible variety to one; and, therefore, if a conjecture is hazarded without any grounds, it is next to a miracle if that conjecture shall be true. Consequently, if we have no indication or any other clue to guide us to a reason, in any one matter of natural history, or

indeed in any one matter whatever, the chances are infinite to one, that any reason which we may in our fancy assign shall be the right one.

This proved to be remarkably the case in the matter of the swallow tribe, and so inveterate was the error that naturalists, almost without exception, and the great Linnæus among the rest, fell into it, although it was at variance not only with the common habits of air birds, but with the whole economy of warm-blooded animals. The reason assigned for this first and last appearance of the swallow tribe when seen skimming the surface of the waters was, that they plunged into the head of the stream, where they passed the winter in a dormant state, and then came up again in the spring; and some learned persons alleged that they had seen the ascent from the water with their own eyes, and entered into the details of it with as circumstantial minuteness as if it had been a truth not only within the limits of possibility, which this was not, but substantiated by general evidence to every part of its occurrence. This very strongly shows the danger of speaking, and especially of writing, upon subjects of natural history, without at least some knowledge of physiology and of the general laws and economy of nature; which, by the way is the reason why we have, in this work, which is framed and intended expressly for general readers—that is, for the great body of the people, and not for mere naturalists,—have been, upon every possible occasion, so anxious to blend the physiology and the relation to the rest of nature with the description of every animal.

When the least attention is given to the subject, the absurdity of hybernation under water, in the case of the swallows, becomes very apparent. There is no warm-blooded animal that can so hybernate,—not even the whale or the seal; nor does it appear that they can sleep there, though they, as well as many of the aquatic birds, can sleep floating upon the surface: but we know of no animal that does or can hybernate on the surface of water; and, indeed, to place an animal on the surface of the water would be putting it in a state of peril to which we have no parallel even in nature. It would be at the mercy of winds and waves, and enemies of all kinds, without any means of protection or power of defence; and we may safely say, that it would be wholly inconsistent with the wisdom and goodness of the Creator, that any one race of beings should be thus abandoned to ruin. Still a warm-blooded animal *might* exist though thus cast upon the waters. Under water is another matter, however; and when once any creature has breathed the pure air of heaven as part of the natural functions of its living system, it can no longer bear to be immersed in a flood of the density of water for any length of time.

Swallows moult their feathers between the time of their disappearance in the autumn and their return in the spring; and this is an operation which could not be carried on under the water: besides, there are few birds which hybernate in any way; none, indeed, which do this habitually; for the few that have been got under hedges and in other places of shelter, apparently lifeless, have always been individuals which met with hindrances which their powers were not able to overcome. Even among the mammalia, the species which hybernate are all sluggish in their general action, cold in their system, and slow and limited in their circulation and breathing; for even on the mountain-tops, or the margins of the never-thawing ice

at the extremity of our continents, we do not find such an animal as a hare passing the winter in a dormant state. On the other hand we find that, even in regions near the equator, many of the reptiles which have a cold system and a sluggish circulation remain dormant for part of the year. The necessity of feeding and of breathing, and also the natural heat of many animals, are in proportion to that animal's activity, for the activity is part of the same system as the rest; and as birds feed more and breathe more than mammalia of the same size and weight, they are also more warm in their temperament, and on that account both less fitted for hybernation and less disposed to it.

Flying is the most severe motion which any animal has to perform, because the flying animal has both to bear itself up in the air and to make progress, whereas, in the case of a walking animal, the weight is borne by the ground, and the moment that it ceases to have progressive motion, it begins to be at rest, or in a state of partial repose. But, even when a bird hovers in the air without making any progression in distance, it is not in a state of even partial repose, as it still has to bear itself up in the air, which, in the case of even the lightest bird, and the one whose plumage is the most flocculent and takes the greatest hold on the air, requires a considerable exertion of muscular energy.

The swallow tribe are more completely air birds, and pass more of their time on the wing, than any other birds which inhabit or visit the British islands. Some of them, the swifts for instance, which are the highest flyers, and which get their common name from the rapidity of their flight, are generally sixteen or eighteen hours on the wing every day at that time of the year when they have their broods. During these hours, they cannot, on the average, move over less space than a thousand or twelve hundred miles; and, if we consider the number of loops and doublings which they make, the exertion, upon one of their long days, must be as great as would carry them at least two thousand miles in one day, so that, at the rate of its ordinary motion in hunting for its food in the sky, a swift could fly round the equatorial circumference of the earth in less than two weeks.

This is a degree of exertion with which we have nothing at all comparable in any animal that walks or runs upon the ground. Some of the swiftest of these can move at the rate of fifteen or perhaps twenty miles in the hour; but there is none that could continue this for several hours, or even for one hour, without being exhausted. There is no miracle in the motion of a flying animal, any more than there is in that of the slowest creature which crawls upon the earth. The principle is the same in them all, though differently modified and furnished with different organisations. And this fact of adaptation runs through the whole, that, in proportion to the action must be the means of repairing the waste occasioned by that action; and among these means respiration is one of the chief. When we make an over-exertion in speed, the lungs are the first part of the body upon which the effects of that over-exertion is felt; and we pant for breath long before we feel any weariness of the limbs. The fatigue of moderate exertion long continued is of a different character; it is felt in the muscles of the parts exerted, while there is no uneasy sensation in the lungs; and it is worthy of remark, that the pulse is rendered both

harder and quicker, and therefore the circulation increased, by that rapid exertion which fatigues the lungs, while in the opposite case, if the pulse does not become slower it becomes more feeble, which equally indicates a diminished circulation.

The motions of the swallow tribe are, as we have said, and as any one may see, very constant and very rapid; and their quantity of respiration and need of food must, according to the general law of nature, correspond. Their labour in flight is even greater in proportion to the rate of their going, than that of more slow-flighted birds. Feathers that take much hold on the air would be the very worst adapted for them, and accordingly all their feathers are firm and smooth; so that the keeping of themselves up is a matter which requires constant exertion. The auxiliary breathing which they have in supplement to the mere action of the lungs (see the article *BIRD*), no doubt prevents the exhaustion of these organs; but still the action of the whole bird is not the less, and the circulation must be in proportion, otherwise the general law of nature would be at an end, and the living world would become a mere mass of confusion.

All these circumstances show, in the clearest manner, that swallows cannot possibly hybernate under the water, or anywhere else. And why should they? The very same powers which they exert every day are competent to carry them from Britain to Africa between sun and sun; and, when they have this power of shifting their place with the seasons, it would be letting this run to waste to suppose that they should in any manner hybernate. There is another consideration, which, though very obvious to those who attend to such matters, it may not be improper to mention; all the tribe are dark, approaching to black; of that very colour, in short, upon which variations of temperature have the greatest effect; and this must co-operate with the falling off of their food, in sending them from the northern countries when the cold weather begins to set in.

That the swallow tribe should appear over the waters when they first arrive in our latitudes, and resort to the same places before they take their departure for the season, is also quite natural, and what, from the circumstances of the case, we might be prepared to expect. The whole race feed upon winged insects, which they capture while on the wing; and the waters are the places over which insects appear first in the spring, and linger longest in the autumn. In the autumn, however, the insects are not so directly over the water as they are in the spring; for by that time of the year the greater number of those insects which commit their offspring to the waters, have performed that, the final purpose of their brief duration in the winged state, and have ceased to exist.

From their activity, their very general distribution, and the rapidity with which they perform their migrations from country to country, the swallows are a most valuable race of animals; and in all countries they resort to the very places where their services are most required, and perform them in a way which can be followed by no others of the feathered race. The common house-fly, which, though hardly known in wild nature, follows man in all his migrations; and though it too has its use, its powers of multiplication are so great, that if there were not some means of keeping it within bounds, it would be an absolute

pest. It is most abundant where the situation is most rich and warm; and as it is a scavenger, it resorts to those places in greatest numbers which are kept in the worst order. But even where there is the greatest attention paid to cleanliness, the house-fly still makes its appearance; and thus, the house-martin comes along with it and regulates its numbers, by feeding itself and its brood upon the overplus. Many of the other flies which are captured in the upper air by other members of the swallow family, are captured while winging their way for the purpose of depositing their eggs in situations where the grubs would be very injurious to the vegetable crops; and it is probable that, in that soft and mirky weather before rain, during which swallows and swifts are so busy in the upper air, some of those small insects, the larvæ of which are so annoying to cultivation, take to high flight for the same purposes. It is well-known that, were it not for birds of some description or another, and the greater number of those in our latitudes are migrant birds, retiring to other climes in the winter, the vegetable productions of the earth would be destroyed in one season. Against these little creatures man has few direct defences within the range of his arts; and it is on this account that the insect-feeding birds are so very valuable. In the case of the swallow-tribe we cannot decide by actual observation what it is that they capture as they dart along the sky and skim the surface of the pools with so much activity. But their activity, and the fact of their finding their food in situations where no other birds can, are abundant proofs of their use in the economy of nature. Nor should we forget that it appears to be to man that they are more especially useful; for with us at least they do not resort to the wild, cold, and mountainous places, but to those which are rich, thickly inhabited, and in a high state of cultivation. There are many of the more northerly parts of the country where, at a distance varying from five to ten miles from the sea, the surface rises to the height of four or five hundred feet, and the climate is exceedingly cold and bleak. In these places winged insects are few, and there is not one of the swallow-tribe to be seen; but when the steep is descended, though the horizontal distance may not be above a mile or two, insects appear in swarms, and swallows are regular visitants. So are they in the inland villages, which lie between those coast-hills and the central mountains; and they are often found upon the latter at heights exceeding the very summits of the province. The general history of these active and interesting birds is, however, a subject upon which volumes might be written.

The whole of the race are strictly insectivorous, and never destroy any thing that is useful to man, however much they may contribute to the preservation of many things that are valuable. Still in their way they are a kind of birds of prey, answering to the diurnal action of the *accipitres*, though the prey is different.

The general characters of the genus are well marked and easily remembered. They are all very thickly formed in the anterior part of their bodies, so that the whole mass is concentrated on the axis of the wings, and they taper off in beautiful curves toward the posterior extremity. Their wings are long and pointed, and remarkably compact in their texture, so that they can undergo a great deal of fatigue without injury. Their tails are produced, in

general very stiff, and in most of the species very much forked. All the extremities of their apparatus of flight are in fact pointed, and they can turn on these points in a very singular manner, flying horizontally or on edge, or at any intermediate angle, apparently with equal ease. The power of the tail appears to give them as much facility of ascent and descent as they have rapidity in forward flight; and as their prey is much more minute than that of even the smallest of the diurnal accipitres, they are endowed with corresponding capacities for finding it. They beat the air with more rapidity and grace than the birds of prey do the ground under them; and the smaller ones, which do not fly above the usual range of the short-winged hawks, assail them with great determination when they make their appearance. It is natural to suppose that their sight is very acute. Their feet are very small and feeble as compared with the power of their wings, but they are not walking birds, and rarely if ever feed upon the ground. Some of them have the foot with all the four toes to the front, or rather all so placed that the claws shall press toward the centre of the foot when the joints of the legs are bent. This enables them to hold on upon upright surfaces, to which no other birds can adhere; and they even, as occasion renders it necessary, bring the tail and the wings to act in aid of this. Their bills are flattened, very broad at the base, generally hooked at the top of the upper mandible, and turned up at that of the lower, but they are without any notch, and the sides rarely close for the whole of their length. For the capture of insects they are very efficient bills, but they are not at all adapted for any purpose of hostility against larger animals. Their gape is remarkably wide; and as they are whisking about on the wing catching flies one can often hear the snap of their bills.

They are sometimes arranged into two subdivisions of swallows and swifts, of which the latter are the more lofty flyers, and probably the more characteristic birds; but we shall not go into the minutiae of the systematic arrangement. We shall first notice those that are to be seen in the British islands, and then name one or two of the more remarkable of the foreign ones.

THE CHIMNEY SWALLOW (*H. rustico*). This is the only species which, with us, is called a swallow, the others being either martins or swifts. It is understood to hatch and breed in Africa, probably to the south of the equator, in our winter, which of course answers to the spring in that country, and to perform its great annual moult about the month of February. Soon after this it begins to migrate northward, and arrives in England about the end of April, at which time it is in fine plumage. The birds speedily disperse themselves, reaching the most northerly parts of the country by the end of the month. They form their nests in chimneys, in out-houses, ruins, and the faces of rocks, but not at any very great elevation. They build with mud, and line the nest with feathers, but do not cover it with a dome. The eggs, in one hatch, are not more than four in number, but in the warmer parts of the country they breed twice, the one hatch being able to take to the wing in June, and the other early in September. In more northerly places they breed only once, and the brood are fully fledged in July, or the beginning of August. They generally take their departure about the end of September, but the time varies a

little with the character of the year. They generally breed in considerable numbers in those spots which afford them favourable nesting-places and abundance of food; but they cannot be said to be casual at those times, as each pursues its own prey and retires to its own nest. When, however, the labours of the year are over, and they begin to prepare for their journey, they do associate in considerable numbers, sitting on the house-tops, or skimming over the humid meadows, in which the birds probably at that time, contrary to their usual habit, roost upon the ground.

Swallow.

The general colour of the swallow is black, with reflections of greyish blue; but in this respect they are subject to some variations, for some are so pale that, if colour alone were the criterion, they might be taken for different species, and occasionally, though much more rarely, they are albinos. The throat and forehead are deep reddish brown, and there is a white spot on the inner web of each of the tail-feathers, with the exception of two in the middle, which are the shortest; the lateral tail-feathers are very long, and this gives a remarkably forked appearance to the tail, so much so, that "swallow-tailed" is a common name for any appendage which is divided in this manner at the end. Swallows are very active and interesting little creatures, whisking about over the surface of the pools, and in other situations where winged insects are numerous, on those days, and at those times of the day, when all the children of nature, except the insect tribes, are still. They glide and dart about with great lightness, and apparently very little motion of the wings, so little indeed, that every single stroke appears to impel them on as if they were shot from a bow. Nor are their turnings on the wing less worthy of remark; for they can double back, not merely at an angle, but at a very acute angle; and though this is done with so much rapidity that one cannot observe the action of the different parts, yet there is a sort of twitching sound, as if some of their fan-feathers struck smartly against each other; but this twitching sound on the turn must not be confounded with the snap of the bill which the bird gives in catching its prey.

**THE HOUSE-MARTIN** (*H. urbica*). This is perhaps the most interesting to man of the whole swallow tribe; and though the house-sparrow is a much more constant attendant on human dwellings, it is not nearly so interesting as this little periodical visitor. This is the "martlet" of the heralds, and was by them described as footless, or a creature committed to the free air alone, and thus it became emblematic of those

younger branches of families which the most absurd and unwise law of primogeniture cuts off from any share of the paternal estate. It is worthy of remark, as concerns this same law, that there is not the slightest approximation to it on the part of any creature when in a state of nature; and though we are not, of course, to take the example of any animal as our rule of action, yet, when the example, and the voice of universal nature, are against us, we can hardly be right. Every one must remember the beautiful allusion made by the gallant Banquo to the nests of this bird found on the cornices of the castle of his treacherous host; and the reader who chooses to turn to that exquisite passage, will see with what truth the poet has not only described the habits and manners of the bird, but has shown the distinction between it and its congener, the swift, with equal force and truth:—

"This guest of summer,  
The temple-haunting martlet, does approve,  
By his loved mansionry, that the heaven's breath  
Smells wooingly here: no jutty, frieze, buttress,  
Nor coigne of vantage, but this bird hath made  
His pendent bed and procreant cradle: where they  
Most breed and haunt, I have observed, the air is delicate."

Nothing can be more graphic than this; for we have observed that, in those uplands of the north, which do not deserve the name of mountains, or even of hills, but which often consist of a species of clay-gravel, which is perfectly sterile, and in which the stones are so impregnated with the cold salt of iron, that they literally consume the earth around them, as if every stone were a canker—we have been in the habit of observing, in such places, that there is not a single swallow to be found; but if some clear stream, with alternate banks of dry sand and soft green sward, breaks the monotony of such a desert, and if the lively "clack" of a mill, as is generally the case, is heard, then the windows of the miller's house have their swallow's nest in each corner, and may be seen whisking across the mill-pond and along the stream with so much industry and glee, that one feels, or, which comes to the same thing, fancies—that a remarkable transition from the most chilling to the most balmy atmosphere has been made in less than a single furlong of ground. Nor is the distinction between the swallow and the swift less true to nature. The latter birds couple on the wing, and perform their rites in the air; but the nest—"the pendent bed and procreant cradle"—is the place where the swallow performs all the labours of the season. The most wonderful circumstance connected with those allusions is their perfect truth, at a time when books written professedly on natural history, by men who assumed the character of naturalists, were full of gross and palpable absurdities; and those exquisite touches of nature which this foremost of all poets throws into his works, and throws in with apparently no effort on his part, are given by him as truths well known to those whose occupation cannot be considered as favourable to the professional study of natural history. Banquo, who makes these beautifully philosophical remarks on the house-swallow, was a brave and gallant soldier, but nothing else.

The house-martin finds out the abode of man in almost every part of the world, at least in every part where it has a chance of finding food for itself and its young; and it is rarely found amid places which are deserted and in ruins. It is probable that

the great attraction for it is the house-fly, for that fly is found only in the neighbourhood of houses, and is rare, indeed, even in those wild woods where winged insects abound the most. It is astonishing to what an extent so small a creature as this house-fly plays the scavenger, and reproves, by the countless swarms in which it appears in houses toward the latter part of the year, the slovenliness of those to whom the charge of such houses is committed. The house-martin is not quite so dashing a bird as the chimney-swallow; its wings are rather shorter and less pointed, and the external feathers of its tail are not so much produced. Still the house-martin is the prettiest bird of the two, and its familiarity makes it an especial favourite. The whole of the upper part, with the exception of the rump, is black, brownish-black on the tail-feathers and the quills and coverts of the wings, and bluish-black on the rest of the body. All the under part is white, of a very pure tint, and the feathers on the sides of the neck break finely into each other. The chief difference between the sexes is, that the breast of the female has a slight greyish tinge, while that of the male is pure white. The tarsi and toes are covered with whitish down, but in no very great quantity.

Martin.

The house-martin is not only the most familiar of our swallows, but it is also the first to reach us in the spring, and the last to leave us in the autumn. As the whole race comes from southern climates, returning to those climates again when the season which is favourable to their habits in our country is over, they appear first and last in the more southerly places; but still they are not long in distributing themselves over the country; and it is highly probable that the greater number of them frequent the same breeding-places for a number of years. If they can build under a projection, which will keep the rain out of their nests, they prefer such a situation; but if not, then they construct a dome to the nest. Those nests are often in curious places. White mentions one which was built in the wing of an owl which had been nailed to a barn; and Jesse mentions one which had not only constructed its nest, but performed its incubations and reared its brood, on the knocker of the hall-door at a gentleman's house in Warwickshire. When the door was opened the bird quitted the nest

for a little, but returned when the door was closed. The winning ways of house-martins, their attention to each other and to their young, and their neat appearance, all tend to render them great favourites; and we believe that, in those parts of the country where there is any feeling of nature among the people, the schoolboys would be considered as acting as sacrilegious a part, in destroying the nest of a house-martin, as in plundering that of a sky-lark, whose glorious matin-song charms even the rustic into feelings of respect and gratitude.

The structure of this swallow's nest is well known. It is formed of mud worked with moisture, much in the same way as the mud walls of cottages in some countries, or as that combination of mould which engineers use for "puddling," or rendering water-tight the banks and bottoms of canals in porous soils. This structure being usually formed in the dry and warm weather, and applied in small quantities, so that each layer consolidates before a fresh one is applied; the texture is very firm and compact, and very nearly impenetrable by water, and insoluble in it. This is also the character of those walls which are constructed wholly of loam or mould, in the manner which is called building *en pise* in some parts of France; for these are more dry and durable than walls of stone or brick.

Some have alleged that there are certain glands in the stomach of those swallows which build compact nests, either of mud, as is done by the species under consideration, or of gelatinous matter, as is done by some others hereafter to be described, which secrete a glutinous substance that assists in giving firmness to the nest; but the nests of common swallows do not contain a trace of any such matter in their composition; and it is very improbable that there is any such matter furnished by the stomachs of those species which construct the gelatinous nests. It is true that we are not very well informed as to what the substance is of which those nests are constructed; and it is also true that there are peculiar glands in the stomachs of those swallows, of which, owing to our ignorance of the general habits of the birds, we do not know the use; but though we are ignorant of the particular matter of which the nests are formed, and also of the particular uses of those glands, it is not a very philosophical proceeding to apply our ignorance of one matter as an explanation of our ignorance of another; and yet this has often been resorted to and been exulted in as something of no common scientific depth by men of high name in comparative anatomy and animal physiology.

The safest way of avoiding such blunders as these, or if they deserve a gentler epithet, such *per saltum* conclusions, which fairly leap across the dark place without throwing any light upon it, is to have recourse to the general analogy of nature, and see whether that would be violated by our supposed discovery. Now we are not aware that there is any warm-blooded animal which elaborates any substance in glands or any other apparatus in the stomach, for any purpose saving the preparation of food either for itself or for its young; which last is understood to be, in part at least, the case with the stomachs of pigeons; nor is it in warm-blooded animals only that we find the stomach confined to the single function of nutrition; for in those invertebrated animals which elaborate shells, and spin threads, and weave webs, and form so many other curious structures, we always find that there is a distinct and specific structure, or apparatus

in the animal, specially adapted for this purpose, and having nothing to do with its digestive system; but requiring a process of secretion in addition to that of assimilation. We mention this circumstance in order to caution the reader against being carried away by that analogy of double ignorance, which is more frequently a stumbling-block than many would be apt to suppose. That we are equally ignorant of two subjects constitutes a certain sort of resemblance between them in our apprehension, but it is not a resemblance from which any conclusion can be drawn.

House-martins are very industrious little creatures; and in those parts of the country which are best adapted to them, they are understood to rear three broods in the course of the season; one in May, a second in June, and a third in July. The hatches do not exceed four or five in number, and each incubation lasts about fifteen days. In the intervals the house-sparrows sometimes take possession of the martins' nests; and though the martins are unable to expel the intruders, it is said that they sometimes build them in.

THE SAND MARTIN (*H. riparia*.) Is the smallest of our British swallows; and it is shorter in the wings and less dark in the colour than those which have been mentioned. Its style of flight is probably as continuous as that of any of the others, if we except the swift, but it is not so bold or discursive. The sand-martin, or bank-swallow as it is called, is brownish black on the upper part and the breast, but white on the remainder of the lower part, and also on the chin and upper neck; upon which latter the white forms a collar nearly halfway round.

This species arrives at least as early as any of the others, and is as late in quitting the country; but it differs from them in the places to which it resorts, and also in its habits. It does not necessarily come near the abodes of men, though if such ground is suitable for its purpose, it is by no means a timid bird; and it is by no means uncommon to find the house-martin very abundantly all over a village, and the sand-martin as plentiful in the sides of a steep bank at the entrance of the village.

In constructing of their nests, sand-martins are excavators, not builders; and they choose the bold and abrupt faces of banks, where the soil is dry and not over-hard, but where it is not likely to be decomposed or washed away by the rain. Firm sand appears to suit them better than any thing else; and where a road has been cut to a considerable depth through a sandy knoll, martins generally find it out and drill it in holes for their nests. Such places are also in general warm, and abound with flies, so that the birds have plenty of food; but under equal circumstances, they prefer the vicinity of water, over the surface of which they are very industrious.

When a colony first take possession of a new bank which has been opened to them, the scene is a busy and far from an uninteresting one. They attack it with mattock and shovel, the bill answering for the first and the claws for the last. The pair work incessantly at this excavation; but as the entrance is not larger than to admit one bird, they do not work in company but by turns, the one carrying on the excavation while the other is feeding. As they labour hard, and live upon small prey which they catch on the wing, their life is a busy one. But still the alternation of digging and feeding appears to afford them considerable relief, as different parts of the body come

into their most severe action during the two tasks. The excavation for the nest is often made to a considerable depth into the bank; and, as is the case with all birds which mine into deep banks, the entrance is made sloping upwards, so as to render the entrance of wet impossible. After the birds have excavated these nesting places to the necessary depth, they line the interior with vegetable fibres and feathers; but as they have more natural shelter from the depth of the excavation, which is often as much as three feet, they are not so careful in lining the nest as those species are which breed in more open places. The eggs are rather more numerous than those of the house-martin; but it is probable that the incubation lasts longer; and it is certain that the birds take more time before they are fledged; and there are not so many broods in the year. The young birds have rust-coloured margins to the feathers on the upper part; and in this marking, the female is intermediate between the young and the male.

Of the *hirundines* which we have now mentioned, the martins are perhaps the most characteristic as British birds; and they are probably more exclusively birds of that migration which takes place between Europe and Africa, nearly in the line of the meridian, than any others of the genus; for though birds of this genus are found in almost every part of the world, north or south, most of them have more the character of our swallows than of our martins. These foreign species are so numerous, their habits are so little known, and those which are known, in general agree so closely with those of the species with which we are familiar, that we must confine ourselves to mere notices of a few of the more remarkable; and before we do so we shall advert to the swifts, as British birds, which, though very closely resembling the swallows and martins in their general habits, have sometimes been arranged and described as a separate genus under the name *Cypselus*.

THE COMMON SWIFT (*C. apus*). Though not altogether footless, as the epithet *apus* would lead us to suppose, is yet worse supplied in feet available to any purposes of locomotion, than perhaps any other British bird. It is true that some of the aquatic birds are as ill adapted for walking as the swift is; but then their feet are all swimming feet, and thus adapted for motion of another kind, and the reason of their answering so ill for the common purpose of walking is chiefly or entirely their superior adaptation to that of swimming. The swift, on the other hand, is no swimmer, and though it partakes in so far of the habit of the race generally as to be able to strike the surface of the water as it darts along on the wing, yet even this habit is not nearly so strong in it as in the swallows properly so called. The foot of the swift is remarkably short, with all the toes turned forwards, and the tips of the claws directed toward the centre of the foot; it is thus a perching foot, but it is adapted for sticking to the asperities of upright rocks and walls, in which the bird is greatly assisted by the great length of the wings and the tail, and the peculiar structure of each, which consist of very fine feathers successively overlapping each other, so as to give great stiffness to the part, at the same time that it is comparatively light.

Of all our birds, the swift may be said to be the most lofty inhabitant of the sky, and the one which is most constantly upon the wing, and its structure corresponds with this habit, for our swift is our best

winged bird in proportion to its size. The weight of the swift is about an ounce; its length nearly eight inches; its breadth about eighteen. The bill is black; irides dusky; with the exception of the chin, the whole of the plumage is black, the chin being whitish. The wings are extremely large, and the legs so short that it rises from the ground with difficulty; the legs and toes are black, and the tail forked. The foot is the principal structural character in which the swift differs from the swallows.

Swift.

When we state that the swift is the loftiest inhabitant of the sky, we do not mean to say that it rises higher than many other birds when migrating or even when beating about for their prey, but the swift feeds in the upper air, and is the only bird which habitually does so. The swallows feed lower down, and the nocturnal birds, which catch insects on the wing, feed lower still; but when we find swifts particularly on the alert in their peculiar style of insect-catching, they are always driving along and wheeling and screeching at the very top of the sky. Of course swifts are confined to places that are fertile and comparatively low, because it is in such places only that a sufficient supply of insect food is found for any of the race; and it would be useless to suppose that any bird could procure a living in the thin air over the mountain tops; but still we can observe that beautiful gradation in the structure, the habits, and the haunts of the swifts, which is traceable in all the swallow tribe. Of our species the sand-martin is the weakest in the body and the least powerful on the wing, and it builds in holes of the earth, and flies low over the surface of water and over ground which abounds in winged insects, which rise during the day, but not to any considerable height. The house-martin comes next in order, building in the angles of windows, or in the eaves of houses, and rarely getting much above house-height in its ordinary flying. The swallow builds in the chimney, is better winged than the martin, has the tail more forked, and can pursue a bolder flight; and accordingly we find it flying higher and straining more vigorously on the wing than either of the martins. The swift nestles above house-height, in the crevices of steeples and towers, and the crannies of rocks, where it constructs its nest wholly of vegetable matter and feathers, without any attempt at mud building. Though the swift is better formed for activity than any of our other summer birds, and is in reality more active, the smaller number of its brood shows that the place which nature assigns it is on the very confines of that chill atmosphere in which no living creature can sub-

sist. The eggs are rarely, if ever, more than two in number, of a white colour, and considerably elongated. The female is a close sitter, and while she is on the nest the male bird hunts very industriously in the neighbourhood, and is ever and anon serenading her with his harsh and discordant screech. At night the two birds are housed in the same crevice; but whether the male actually takes a share in the labour of incubation has not been very clearly ascertained.

The height to which swifts fly depends a good deal upon the state of the weather. When the atmosphere is pure and dry their flight is most elevated, but when it is moist they fly much lower, and sometimes come down so far as almost to touch the surface of the water. In those troubled states of the atmosphere which usually precede thunder-storms in our warm months, they are more active than at other times, and also more varied in the elevation of their flight. They seldom, if ever, alight on level ground, because their short legs and long wings would make rising from such surfaces a matter of considerable difficulty. The swift is among the last of our swallows in coming, and it is also the first to depart; and this shows that the place where they feed is the one which is the latest in producing, and the first which ceases to be productive. The quantity of their motion during the summer days is immense, for they are often sixteen hours not only on the wing but in vigorous and continued flight, during which time they travel over as many hundreds of miles as they fly hours. Such a rate of flight, and power of continuance on it, renders migration a very simple matter with the swifts, and it is not too much to say that they breakfast in Africa and roost in England on their arrival, or breakfast in England and roost in Africa when they take their departure.

**WHITE-BELLIED SWIFT (*C. alpinus*).** This species, which is of comparatively recent observation as a British bird, and has hitherto been noticed only as a straggler in the south-east of the island, differs in colour, in size, and in some other particulars from the common swift. With us the common swift is deep black, with only the chin dull white, though the black becomes brownish toward the close of the season. The Alpine swift is brownish on the upper part, and has the belly white. It is also a larger bird, being about nine inches long. It has the bill black, the feet flesh-coloured, the sides mottled with a dusky colour and white, and a brownish grey collar on the neck.

Though a rare straggler in our island, the white-bellied swift is a very fine bird, and perhaps has more "dash" about it than the species with which we are more familiar. Like the other, it is a migrant, but its migrations are of a more southerly and easterly character. Its range is from an indefinite distance, southward, in Africa, to the average line of the Alps, though we believe it is by no means common northward of the summits of those mountains, excepting in the Tyrol, where it is said to range farther to the north than in more westerly longitudes. In coming and going it is found in considerable numbers in the islands of the Mediterranean, and on the coast of Italy; but these are not its proper habitats. It arrives in Upper Lombardy and the adjacent countries about the beginning of April; but its first haunt is over the pools and marshes, so that even this bird might have been described as hibernating in the water, with as much propriety as our common swallow. It remains

over those lowland and marshy places for about a fortnight or three weeks, after which it betakes itself to the mountains and begins in earnest its labours for the year. It nestles in the clefts of rocks which stand high and beetling in mid air, among which it dives about with great vigour and rapidity, wheeling and sporting as if it were wholly composed of wings, though its little crab feet are always in readiness to clutch and maintain their hold on the least irregularity of the rock, whenever they require a pause in their aerial motions. They usually fly in society, not in very great numbers; but there are some curious instances of consent among them; for while one clings to the rock, a second clings to the first, a third to the second, and so on, till the whole form a sort of chain of birds moving in the air. What may be the reason of this singular mode of clinging to each other it may be difficult to say, but it must be momentary, as the birds remain but a very short time in this posture before they are wheeling and screaming with the same activity as before.\* Such of them as nestle in the Appenines appear earlier in the season, and set about the construction of their nests. Those nests are small for the size of the birds, but they are carefully put together and carefully lined with soft feathers. In those southerly places they have two broods in the season; the first, consisting of three or four, being matured about the middle of July; and the second, consisting of two only, about the end of September. Those which resort to more upland and northerly places are said to have only one brood in the year, consisting of two eggs, as is the case with our swift. In October they usually take their departure for more southern climates; but they are not so constant in their time of departure as in that of their arrival. The Italians, who are much more given to eat small birds than we of a land more abundant in beef and mutton, esteem the young of these swifts as delicacies for the table; but after their muscles have been seasoned to the sky by a journey to Africa and back again, they, like the muscles of all other birds inured to vigorous and continued flight, become somewhat tough for mastication.

When these birds retire to rest after the severe labours of the day, the male and female squat down together upon the nest; and when they do so they may be touched, or even taken, with the hand. The precise range of this species in longitude is not very well known; but it is not at all improbable that they may reach as far as the east of Asia, or even to the oriental islands; for there are several species in those parts of the world whose characters are not very well ascertained; though it should seem that some of them, at least, bear a considerable resemblance to this species. It should seem, however, that the long-winged swift (*C. longipennis*) is a distinct species. It has the upper part of a bright dark-green colour, with the wings and tail of a bluish green, except the quills next the body, which are white. There is a spot of maroon brown on the ear coverts, and the under part of the neck is ash-coloured, with the exception of the middle of the belly, and the under tail coverts, which are white. The rump is greenish ash, the bill black, and the feet reddish. The male is without the spot on the ear coverts. The length of the head is between eight and nine inches.

THE GREAT CHINESE SWIFT (*C. Sinensis*) is another oriental species, having some points of resemblance to the white-billed swift of southern Europe;

but it is larger in size, and differently coloured. It is brown on the upper part, with the top of the head bright russet, a brown band across the eyes, surrounded with small white feathers. The bill and feet are bluish grey; and the length about eleven inches and a half.

THE RUFFED SWIFT (*C. comatus*) is an inhabitant of the oriental islands. The upper parts, the neck, the breast, and the belly, are bronze green; the sides of the head are furnished with long and straight feathers of a white colour, which form a sort of hood over the base of the bill, and also a kind of crest on the nape. The feathers on the other parts of the head are also long and pendent, and they are bronze green. The quills and tail feathers are bright green with metallic reflections; the belly and the under tail coverts are white; and the bill and feet are blackish. The tail is very much forked. It is a beautiful species, but it is small, the length being little more than five inches and a half. The habits and migrations of these southern species are little known; and some of them have, in all probability, been confounded with the swallows, from which, however, the real swifts can always be easily distinguished by the shortness and peculiar form of their feet, and the elevation and style of their flight.

THE GREAT SWIFT (*C. giganteus*) is a native of Java, and most probably of several other south-eastern isles. It is nearly eight inches in length; the general colour of the upper part is blackish brown, with the exception of the middle of the back and the scapulars, which are ash-colour without any reflections or gloss. The top of the head, the nape part of the coverts of the wings, and also of the under tail coverts, are of a deep green with very brilliant reflections; the greater coverts and quills of the wings are black with brilliant reflections; and some of the quills have the point and the shaft prolonged, and without webs for some part of their length. There is a white band on the thighs, and the tail feathers also are in part white. The bill and feet are brown. The eastern islands are, indeed, very favourable pastures for fissirostral birds, because the air over them swarms so thickly with insects, and though some of the species are migrant in that garden of the world as well as in our more seasonal country, they are, taking them on the whole, much more resident; and though it is difficult to say which are the more characteristic birds in a country so abounding in birds, and so curious as well as brilliant in some of the species, yet the Sunda Islands appear to be especially the head-quarters of the swifts, which are the most rapid and elevated flyers of all insectivorous birds which seek their food on the wing. Whether any of the swifts, properly so called, visit New Holland, has not been so clearly made out; but there are some swallows in that part of the country, though in several respects they differ from ours. The principal one which seasonally visits the east coast of New Holland, is,—

THE JAVA SWALLOW (*H. Javanica*); and we cannot perhaps do better than quote the following account of it from Cayley, as communicated to the Linnæan Society by Vigers and Horsfield:—"The resting-places of these swallows are on the dead boughs of large trees, where I have seen several of them gathered together in the same manner as European swallows on the roof of a house. I apprehend, however, that it is when their young have taken to flight that this occurs.

'The earliest period of the year that I noticed the appearance of swallows was on the 12th of July, 1803, when I saw two; but I remarked several towards the end of the same month, the following year (1804). The latest period I observed them was on the 30th of May, 1806, when a number of them were twittering and flying high in the air. When I have missed them at Paramatta I have sometimes met with them among the North Rocks, a romantic spot about two miles northward of the former place. The natives call the swallow *Berrin-nin*; they told me it built its nest in the hollow limbs of white gum-trees, using bark, grass, hair, or similar substances; but when it built in old houses, it made use of mud. These old houses are the deserted huts of settlers who have abandoned their worn-out farms; and the nests are constructed on the wall-plates, as they are called in the colony. Of the nests, which have been brought to me, I have observed that the outside was made of mud, and the inside lined with feathers. Though I have seen swallows more or less throughout the year, yet it is my belief that they are migratory. The eyes are black.'

The American species, as we have already remarked, are swallows or martins, rather than swifts; and though in their habits they bear a very close resemblance to the species of the eastern continent, and some of them get similar names from the European settlers, it is doubtful whether any of them are exactly the same species. They are very numerous in some parts of the country, and they follow the common seasonal migration of American birds, proceeding northwards in the spring, and returning southward in the summer.

THE AMERICAN CHIMNEY SWALLOW (*H. pelagius*), though sometimes called a swift in the United States, very closely resembles our chimney swallow in some of its characters; but it is rather a smaller bird, and remarkable for the length of its wings, the stretch of which when spread out is twelve inches, while the length is only about four and a half. The sexes very closely resemble each other in colour, being sooty brown, with the exception of the chin, and a streak over the eyes, which are dull white. The naked skin from the bill to the eye is black; the bill is extremely short, hard, and black; the nostrils are placed in a slightly elevated membrane; the legs are covered with a loose skin of a purplish colour, the thighs are of the same colour and naked; the feet are very muscular; the three fore toes are very nearly of the same length; the claws extremely sharp; when the wing is closed it extends an inch and a half beyond the tip of the tail, which is rounded, and consists of ten feathers very little longer than the coverts: their shafts extend beyond the vanes, they are strong, sharp-pointed, and extremely elastic.

The following quotation from Wilson's account of this species will show the habits of this bird, and also what are the resources of chimney-building swallows where the country contains no chimneys in which they can build. "One of the first settlers in the state of Kentucky," says Wilson, "informed me that he cut down a large hollow beech tree, which contained forty or fifty nests of the chimney swallow, most of which, by the fall of the tree or by the weather, were lying at the bottom of the hollow, but sufficient fragments remained adhering to the sides of the tree to enable him to number them. They appeared, he said, to be of many years' standing. The present site which they

have chosen must, however, hold out many more advantages than the former, since we see that, in the whole thickly settled parts of the United States, these birds have uniformly adopted this new convenience, not a single pair being observed to prefer the woods. Security from birds of prey and other animals, from storms that frequently overthrow the timber, and the numerous ready conveniences which these new situations afford, are doubtless some of the advantages. The choice they have made certainly bespeaks something more than mere unreasoning instinct, and does honour to their discernment. The nest of this bird is of singular construction, being formed of very small twigs, fastened together with a strong adhesive glue or gum which is secreted by two glands, one on each side of the hind head, and mixes with the saliva. With this glue, which becomes hard as the twigs themselves, the whole nest is thickly besmeared. The nest itself is small and shallow, and attached by one side or edge to the wall, and it is totally destitute of the soft lining with which the others are so plentifully supplied. The eggs are generally four, and white. They generally have two broods in the season. The young are fed at intervals during the greater part of the night; a fact which I have had frequent opportunities of remarking both here and in the Mississippi territory. The noise which the old ones make in passing up and down the funnel has some resemblance to distant thunder. When heavy and long continued rains occur, the nest, losing its hold, is precipitated to the bottom; this disaster frequently happens; the eggs are destroyed, but the young, though blind (which they are for a considerable time), sometimes scramble up along the vent, to which they cling like squirrels, the muscularity of their feet and the sharpness of their claws at this tender age being remarkable. In this situation they continue to be fed for perhaps a week or more. Nay, it is not uncommon for them voluntarily to leave the nest long before they are able to fly, and to fix themselves on the wall, where they are fed until able to hunt for themselves. When these birds first arrive in spring, and for a considerable time after, they associate together every evening in one general rendezvous, those of a whole district roosting together. This place of repose, in the more unsettled parts of the country, is usually a large hollow tree, open at top; trees of that kind, or *swallow trees*, as they are usually called, having been noticed in various parts of the country, and generally believed to be the winter quarters of these birds, where, heaps upon heaps, they dozed away the winter in a state of torpidity; here they have been seen on their resurrection in spring, and here they have again been remarked descending to their death-like sleep in autumn."

PURPLE MARTIN (*H. purpurea*). This is also an American species, and in its manners it bears no inconsiderable resemblance to the house-martin of Europe, frequenting, like that bird, the habitation of man in preference to more lonely and sequestered places. It is very abundant in the United States; and a solitary instance of dislike to it, recorded by Wilson, is so characteristic, that we cannot resist quoting it. "I never met," says he, "with more than one man who disliked the martins, and would not permit them to settle about his house. This was a penurious close-fisted German, who hated them because, as he said, 'they ate his *peas*.' I told him he must certainly be mistaken, as I never knew an instance of martins eating *peas*; but he replied, with

coolness, that he had many times seen them himself 'blaying near the hife, and going *schuip schuap*,' by which I understood that it was his *bees* that had been the sufferers; and the charge could not be denied." In general, however, the Americans are sensible of the advantages which they derive from these birds in clearing the neighbourhood of their houses of winged insects, which are particularly troublesome in that land of marshes and forests. They arrive in the southern states in February or March, but do not reach the central ones till March or April; and in more northerly places, for their migration extends nearly to the polar confines of the American continent, they arrive in May, and take their departure in August. The ornithologist, to whom we are under such obligations on the subject of all such birds in America as come within his notice, has so well described the accommodations that are made for those interesting little creatures, that we should do them injustice were we to mention them in any words except his own. "The summer residence," says Wilson, "of this agreeable bird is universally among the habitations of man, who, having no interest in his destruction, and deriving considerable advantage, as well as amusement, from his company, is generally his friend and protector. Wherever he comes he finds some hospitable retreat fitted up for his accommodation and that of his young, either in the projecting wooden cornice, on the top of the roof, or signpost, in the box appropriated to the bluebird, or, if all those be wanting, in the dove-house among the pigeons. In this last case he sometimes takes possession of one quarter or tier of the premises, in which not a pigeon dare for a moment set its foot. Some people have large conveniences formed for the martins, with many apartments, which are usually fully tenanted, and occupied regularly every spring, and in such places particular individuals have been noted to return to the same box for several successive years. Even the solitary Indian seems to have a particular respect for this bird. The Choctaws and Chickasaws cut off all the top branches from a sapling near their cabins, leaving the prongs a foot or two in length, on each of which they hang a gourd or calabash, properly hollowed out for their convenience. On the banks of the Mississippi the negroes stick up long canes, with the same species of apartment fixed to their tops, in which the martins regularly breed. Wherever I have travelled in this country I have seen, with pleasure, the hospitality of the inhabitants to this favourite bird."—"About the middle, or 20th of April, the martins first begin to prepare their nest. The last of these which I examined was formed of dry leaves of the weeping willow, slender straw, hay, and feathers in considerable quantity. The eggs were four, very small for the size of the bird, and pure white, without any spots. The first brood appears in May, and the second late in July. During the period in which the female is laying, and before she commences incubation, they are both from home the greater part of the day. When the female is sitting she is frequently visited by the male, who also occupies her place while she takes a short recreation abroad. He also often passes a quarter of an hour in the apartment beside her, and has become quite domesticated since her confinement. He sits on the outside, dressing and arranging his plumage, occasionally passing to the door of the apartment, as if to inquire how she does. His notes, at this time, seem

to have assumed a peculiar softness, and his gratulations are expressive of much tenderness. Conjugal fidelity, even where there is a number together, seems to be faithfully preserved by these birds. On the 25th of May a male and female martin took possession of a box in Mr. Bertram's garden. A day or two after a second female made her appearance, and stayed for several days; but, from the cold reception she met with, being frequently beat off by the male, she finally abandoned the place, and set off, no doubt, to seek a more sociable companion. The purple martin, like his half-cousin, the king-bird, is the terror of crows, hawks, and eagles. These he attacks whenever they make their appearance, and with such vigour and rapidity that they instantly have recourse to flight. So well known is this to the lesser birds, and to the domestic poultry, that, as soon as they hear the martin's voice engaged in fight, all is alarm and consternation. To observe with what spirit and audacity this bird dives and sweeps upon and around the hawk or the eagle is astonishing. He also bestows an occasional bastinado on the king-bird when he finds him too near his premises, though he will, at any time, instantly co-operate with him in attacking the common enemy. The martin differs from all the rest of our swallows in the particular prey which he selects. Wasps, bees, large beetles, particularly those called by the boys *goldsmiths*, seem his favourite game. I have taken four of these large beetles from the stomach of a purple martin, each of which seemed entire, and even unbruised."

This species is very swift in its flight, and wheels and turns with much rapidity and grace. It comes more into the towns of America than the European swallows do into the towns of Europe; and along with its familiarity, the neatness with which it avoids passengers and other objects in the streets, is worthy of admiration. It is rather a large species, being at least eight inches in length, and double that measure in the stretch of the wings. The general colour of the upper part is a rich and deep purplish blue, with very brilliant reflections of violet; but the wings and tail are brownish black. The tail consists of twelve feathers, is considerably forked and margined with purplish blue. The bill is very strong, and the opening of the mouth large; the eye is very full and dark, and surrounded by naked skin of a black colour. The legs are very short, approaching in that character to those of the swifts. The female is of nearly the same dimensions as the male, but it differs a little in colour. The prevailing tint of the upper part is blackish brown, with purple and violet only in scattered spots. The chin and breast are greyish brown; the under sides of the wings of the same colour, but darker; and the belly and vent-feathers are dull white, marked with dusky yellow.

THE BARN SWALLOW (*H. Americana*), is another American species which has a considerable resemblance in its habits to our house swallow. It is a smaller bird, and less powerfully winged than the species last noticed; but it is very abundant, and migratory, appearing in great numbers in the narrow part of central America, especially about Honduras, during the rains which occur between the months of October and February, but as soon as the rains are over, it takes its departure for more northerly climates. Some remarks on the habits of these birds, made by Captain Henderson in his account of Honduras, are worthy of quotation, as pointing out something peculiar in the

habits of birds, in that very singular region of the world. "There is something," says Captain Henderson, "remarkably curious and deserving of notice in the ascent of these birds. As soon as the dawn appears they quit their place of rest, which is usually chosen amid the rushes of some watery savannah, and invariably rise to a certain height in a compact spiral form, and which, at a distance, often occasions them to be taken for an immense column of smoke. This attained, they are then seen separately to disperse in search of food, the occupation of the day. To those who may have had the opportunity of observing the phenomenon of a water-spout, the similarity of evolution in the ascent of these birds will be thought surprisingly striking. The descent, which regularly takes place at sunset, is conducted much in the same way, but with inconceivable rapidity; and the noise which accompanies this can only be compared to the falling of an immense torrent, or rushing of a violent gust of wind. Indeed, to an observer, it seems wonderful that thousands of these birds are not destroyed in being thus propelled to the earth with such irresistible force."

This species of swallow is about seven inches in length, and thirteen inches in the stretch of the wings. The bill is black, the upper part of the head, neck, back, rump, and tail-coverts steel blue, which descends rounding on the breast. The front and chin are of a deep chestnut. The belly, vent, and lining of the wing, light chestnut. The wings and tail are of a brown black, slightly glossed with reflections of green; the tail is forked, the exterior feather on each an inch and a half longer than the next, and tapering towards the extremity; each feather, except the two middle ones, marked on its inner vane with an oblong spot of white; eye dark hazel. The sides of the mouth are yellow, and the legs are dark purple. The female differs from the male in having the belly and vent rufous white, instead of light chestnut. These parts are also slightly clouded with rufous, and the exterior tail feathers are shorter. These birds soon become exceedingly gentle, and are easily tamed; and when kept in a room, they employ themselves in catching flies, and picking them from the garments, &c, it may contain; and they may be occasionally observed calling out of the window to their old companions as they pass it.

These birds are more abundant on the Atlantic side of the Alleghany mountains than they are in the great central valley of North America, and in every place they are more abundant as the country is more thickly settled. They do not frequent the woods and wilds, but rather the close vicinity of the farmhouses, where they make their nest attached to the beams and rafters of barns, and other large out-buildings; and so partial are they to such places, that scarcely an outhouse to which they can find access is without them. Sometimes one large barn will contain several scores of nests, and though the birds build within a few inches of each other, the greatest harmony appears to prevail among them; nor are they subject to the persecution of even the most parsimonious of the German settlers, not being accused of going "*schnip schnaup* near the hif," as is alleged of their congener formerly alluded to. On the other hand, even the superstition of the Germans has come to the protection of these birds; for Wilson found settlers of that country who firmly believed that this kind of swallow protected their barns from lightning, and that if they

wantonly killed the birds the milk of their cows would immediately after become tinged with blood. They build their nests, at least in the middle latitudes of the United States, in the early part of the month of May. The structure is a work of some labour, formed of mud, and rendered stronger by an admixture of fine vegetable fibres. It is in the shape of an inverted cone, about six inches in diameter and five in depth, as measured on the outside; and the lip is generally enlarged in order to allow a resting place for the male when feeding the sitting female, or the two birds when feeding the young. There is no dome to the nest, and such an addition is not required, as it is made under cover; but the inside is carefully lined, first with fine dry grass, and then with soft and downy feathers. The eggs are usually four or five in number, white in the ground colour, and mottled over with small specks of reddish brown. They are, however, semi-transparent, which gives them altogether a slight reddish appearance. It is worthy of remark that in proportion as birds take greater care in providing soft and warm nests for their eggs, those eggs are always more delicate, finer in the shell, and approach more to transparency. Birds whose eggs have this character, are generally close sitters, they are almost all birds of firm plumage and rapid wing, and the greater number of them are migrant. The present species have generally two broods in the course of the season, and thus, while they remain in the United States, their life is a very busy one. There is also a sort of attempt on the part of the old birds to train the young ones to something like habits of independence, or of shifting for themselves in the world; for, before the young venture out of doors, they take a good deal of exercise in flying, along with the old ones, within side the barn or other shelter. Altogether this is perhaps the most interesting species of swallow which is met with on the American continent.

WHITE-BELLIED AMERICAN SWALLOW (*H. viridis*), has sometimes been confounded with the house martin of the eastern continent, but it is different in colour. The European martin is bluish black, and has the rump white and the legs covered with short feathers of a whitish colour. The American species is greenish on the upper part, has no white on the rump, and no feathers on the legs. It is a migrant, and arrives later in the United States than many of the others, and it resorts to the shrubby islands in the estuaries and rivers. The length of the bird is not quite six inches, and the extent of the wings is about twelve. The upper parts are light greenish blue with a rich gloss; the wings brownish black with slight reflections of green; the tail is much forked, the two exterior feathers being about a quarter of an inch longer than the middle ones. The under part is pure white; the close wings extend a quarter of an inch beyond the point of the tail; and the legs are short, strong, and naked of feathers, and of a purplish colour. The nest of this species has the principal part formed wholly of vegetable fibres, without any admixture of mud; but it is lined with a profusion of feathers, which are so disposed as to cover the eggs when the female quits them. These eggs are four or five in number, and of a white colour; and it is understood that the birds have generally two hatches in the course of the year. They are not exclusively insectivorous, but in the end of the season they resort to the swamps which are thickly covered with the candleberry myrtle, and feed upon the fruit of that plant,

becoming in high condition before they take their departure for the winter. When they resort to these places, they generally do it in dense crowds, so that though individually of small size, their accumulated numbers make them objects of some importance to the fowlers, who will sometimes kill from one hundred to two hundred at one shot.

There is a sand martin or bank swallow on the continent of North America; but as it does not appear to differ much from the European one, it does not require any detailed notice; but we may remark that it is singular that this species of swallow should be common to the two continents, when it does not appear that any of the rest are so. In south and central America, there are many species of swallows; but this article has already extended to so great a length, that we shall only mention one or two of the more remarkable. Before doing this, we may state that there is a very considerable difference between the migratory birds of our northern hemisphere and those of the southern one. This is what, from the physical circumstances of the two hemispheres, as well as from the lower latitude to which the land extends in the south, we might be prepared to expect. The openness of the southern ocean, which is never interrupted by ice at any of the three points of Van Diemen's Land, Southern Africa, and South America, admits of a complete circulation of the ocean waters, and of the atmosphere over them, by means of which the characters of the equatorial and polar parts of that hemisphere are kept within their own zones; and thus, though the southern hemisphere is, latitude for latitude, colder than the northern upon the whole, yet the seasonal differences for any one latitude are much smaller; and this circumstance necessarily occasions a corresponding difference in the movements of the seasonal birds. This is not the place for fully working out all the peculiarities of this difference, even though our limits permitted; but without taking this consideration along with us, we should be somewhat puzzled with the fact, that the southern swallows are comparatively resident, or at all events much more confined in their migrations than the northern ones.

THE WHITE-RUMPED SWALLOW OF PARAGUAY (*H. Leucorrhæa*) is rather a social species, and fond of coming near human habitations, and also of following travellers and their mules and horses in crossing the country. It is a resident species in the valley after which it is named, and also in other parts of South America. Its length is about five inches and a half; the upper part blue with reflections; the quills, coverts, and tail-feathers dull black; the rump, a streak over the eye, and all the under part white. This species builds indiscriminately in the thick heads of the palm tree and in holes of the ground, constructing its nest of vegetable fibres lined with hair and feathers. The entrance is in the side, and made so narrow that no animal larger than itself can enter, and so deep that neither the eggs nor the young can be got out without pulling the nest to pieces.

THE DOMESTIC SWALLOW OF PARAGUAY (*H. domestica*) approaches in its manners the swallows with which we are most familiar. It is blackish blue on the upper part, and velvet black on the cheeks, the quills, and coverts of the wing and tail-feathers. The sides of the head are brownish black, the front of the neck and flanks whitish, clouded with brown; the breast and belly white; the bill black; the feet violet

black in front, and reddish behind; and the tail very much forked. This species is very common in South America, resorting to cabins and country houses in thinly inhabited places, and to the churches and larger buildings in the towns. It constructs its nest externally of mud, but lines it with vegetable matter and feathers. The eggs are two or three in number. This swallow is more migrant than the one last mentioned, moving toward the equator during the southern winter, and northward during the summer. Such is a specimen of South American swallows.

HISPA (Linnæus). A genus of coleopterous insects belonging to the section *Tetramera*, and family *Cassididæ*, having the jaws short, with two or three smaller minal teeth. The antennæ are cylindrical, approximated at the base; and the thorax and elytra often clothed with acute spines. There is one reputed British species of small size (*H. atra*), but America is very rich in the individuals of this genus.

HISTERIDÆ (Leach). An extensive family of small coleopterous insects belonging to the section *Pentamera*, and subsection *Clavicornes*, of Latreille, distinguished by having the antennæ short, elbowed at the end of the first long joint, the four posterior legs inserted widely apart, the legs spinose and contractile. The club of the antennæ is nearly round, and then jointed, and the elytra are shorter than the abdomen, and rounded behind. The body is of a very hard consistence, and generally of a square form; the jaws are very strong and horny, and the palpi filiform. In several respects, as in the toothed legs and widely-inserted legs, these insects approach some of the lamellicorn beetles, but in their internal anatomy they seem more nearly allied to the *Silphæ*. The derivation of the name of this group has somewhat perplexed entomologists; they, however, appear to agree that it is derived from *Histerio*, a stage-player, although the cause of such derivation remains unknown. Herbet, indeed, supposes that the short square elytra, with red spots, in some of the species, might have suggested the name, in allusion to the dress of a buffoon. We, however, see a difficulty in the matter when we look to the natural history of the insect, which in England have thence obtained the name of mimic beetles, from the admirable facility with which they feign death when alarmed, by withdrawing their antennæ, and folding up their legs, so as to resemble a small black stone, or a seed; indeed, one of the species is hence called *Seminulum*. They feed upon bones, or other decaying animal matter, as well as upon dung and rotting vegetables. They creep but slowly. Their colours are shining black, or sometimes somewhat metallic.

This family corresponds with the Linnæan genus *Hister*, which, from its great extent, and the modifications of structure in different groups, has been divided into various genera by recent authors, amongst whom the memoirs of Dr. Leach, in the *Zoological Miscellany*, and of Dr. Erichson, in the *Jahrbücher*, are especially valuable. There are about fifty British species divided into the genera *Abræus*, *Orithophilus*, *Hister*, *Dendrophilus*, and *Platysoma*. The typical genus, *Hister*, has the body depressed, the four posterior tibiæ with a double series of spines, and the prosternum advanced beneath the mouth. The species are very numerous, and chiefly distinguished by the number of spines on the tibiæ, the striæ, and punctures upon the elytra and thorax. The type of the genus is the *H. unicolor* (Linnæus), a very abundant species,

of a black shining colour, varying from one-sixth to one-third of an inch in length,

HOG. See SUS.

HOG-NUT is the *Carya porcina* of Nuttall, a North-American tree allied to our walnut. The flowers are monœcious, and the caryas are placed in the natural order *Juglandææ*. They are commonly called hickory nuts, are less grateful than the walnut, but still wholesome and nutritious. The best are those of the *C. olivæformis* and *sulcata*, the kernels of both of which are excellent.

HOITZIA (Jussieu). A genus of handsome flowering plants from Mexico. They rank as greenhouse evergreen shrubs, and belong to *Polemoniaceæ*. Generic character: calyx five cleft, supported at the base by several serrated bractea; corolla, funnel-shaped, the limb divided into five lobes; stamens protruding; capsule three-celled, three-valved, and many-seeded. These plants thrive in a mixture of sandy loam and moor-earth, and are propagated by cuttings.

HOLLY is the *Ilex aquifolium* of Linnæus, a well known evergreen shrub, a native of Britain. The common holly, or holme, or hulver of which we have many varieties, is the only British species of *Ilex*. Here it seldom exceeds the size of a bush, though in some places, both in France and England, they grow forty or fifty feet high. Its prickly leaves fits it well for hedges, and when Dutch gardening prevailed here gardens were portioned out by well-clipped holly hedges. The celebrated Evelyn had one at Sayes-court, four hundred feet long, nine feet high, and five feet broad, which he had planted at the suggestion of Peter the Great, who resided at his house when he worked in the dockyards at Deptford. And in his "Sylvæ," he asks with rapture, "Is there under heaven a more glorious and refreshing object of the kind than such an impregnable hedge, glittering with its armed and varnished leaves, the taller standards at orderly distances, blushing with their natural coral." The finest holly hedges in Britain, or perhaps in Europe, are at Tynningham, the seat of the earl of Hadington, in East Lothian. The holly is a slow growing tree, and the timber is among the hardest of the white woods. It is much used by turners, and especially in the manufacture of Tunbridge ware. The liber abounds with a tenacious liquid, which, when separated by bruising and maceration, is known as bird-lime.

HOLLYHOCK is the *Althæa rosea* of Cavanille, a native of China, and one of the principal ornaments of our gardens. The hollyhock is a biennial, and therefore, to keep up a stock, seed must be sown every spring, usually in a hotbed, and there nursed till the plants are large enough to be put out in the open borders. They are usually planted in shrubberies.

HOLMSKIÖLDIA (Retzius). A genus of two beautiful plants, one an evergreen shrub from Peru, and the other a climber from India. They belong to the natural order *Verbenaceææ*. Generic character: calyx large, spreading, coloured, faintly five toothed; corolla tubular, limb divided into two short lips, the upper one two-lobed, the lower one three-lobed, side lobes short, middle one oblong, entire and deflexed; stamens protruding, bearing oval anthers; style filiform; stigma unequally double; berry four-lobed, clubbed, one-celled and many-seeded. This genus was called *Hastingia* by Smith, and *Platanum* by Jussieu. They grow in any light rich soil, and are propagated by cuttings.

HOMALINEÆ. A small natural order, containing four genera, namely *Homalium*, *Blackwellia*, *As-tranthus*, and *Aristotelia*. These are tropical shrubs or small trees, with simple, entire, alternate, impunctate leaves, and free deciduous stipules. The inflorescence is spicate, racemose, or paniculate; the pedicels without bractea, and the flowers regular and united. Little is known of the general properties of the Homalineæ. *Aristotelia magui* is the maqui of Chili, the berries of which are eatable; they are about the size of peas, of a very dark purple colour, becoming ultimately black, and of an agreeable acid flavour. The native Chilians make a wine of their juice, and in a fresh state they are esteemed as a febrifuge, and reputed to be serviceable in malignant fevers. The bark is astringent, and contains so much gallic acid that it blackens rapidly the instruments with which it is cut. This is the plant which Dombey used with such remarkable success in Chili, in the year 1782.

HOMERIA (Ventenat). A genus of bulbous stemmed herbs, natives of the Cape of Good Hope. *Monadelphia Triandria*, and natural order *Irideææ*. Like all the rest of the order the flowers are conspicuously beautiful, and are cultivated like other Cape bulbs, in a mixture of sandy loam and moor-earth; kept quite dry when dormant, but watered freely when growing. This genus was formerly called *Moræa*, by Jacquin and other botanists.

HOMOPTERA (Latreille). A sub-order, according to Latreille and Kirby (or a distinct order, according to Leach, MacLeay, &c.), of insects separated from the Linnæan order *Hemiptera*, having the wing-covers generally deflexed, of the same consistence throughout, the antennæ mostly short, and terminated by a bristle, and the body convex and thick, with the thoracic segments united into a mass, the first very generally shorter than the second; the proboscis also arises nearer to the posterior part of the head, sometimes even appearing pectoral. All the insects of this group subsist upon the juices of vegetables, which they obtain by the assistance of their articulated proboscis, and sometimes, as in the case of the aphides and sugar-cane fly (*Delphax saccharivora*), the mischief which they occasion is very extensive. The females are furnished with a scaly ovipositor, composed of three toothed saws, lodged, when at rest, in a bivalve sheath at the tip of the under side of the abdomen. With this apparatus they are enabled to make an incision in the leaves or stems of plants, into which they afterwards introduce their eggs.

Latreille divides this sub-order into the three following divisions:—

1. The *Cicadaria*, having the tarsi three-jointed, and the antennæ very short, terminated by a fine bristle, comprising the families *Cicadidææ*, *Fulgoridææ*, and *Cercopidææ*.
2. The *Aphidiens*, having the tarsi two-jointed, and the antennæ longer, without a terminal bristle, containing the families *Aphidææ* and *Psyllidææ*. Latreille also here places the *Thripsidææ*, but its organisation renders this location doubtful.
3. The *Gallinsecta*, having the tarsi one-jointed, terminated by a single claw. The males have two wings, and are destitute of a mouth. The female is wingless, and furnished with a sucker. Comprising the single family *Coccidææ*.

For an account of these families, &c., see the several articles thereon.

**HONEYSUCKLE.** This beautiful genus of flowering shrubs occupies a very prominent situation in the shrubbery and flower garden. It belongs to the class and order *Pentandria Monogynia*, and is better known in the language of poetry as the *woodbine*. It was common in the flower gardens of the ancient Greeks, and we find it a never failing theme with our earliest poets when they wished to furnish a striking emblem of devoted attachment. Thus Chaucer, the father of English poetry, says,

“ And tho that were chapelets on hir hede,  
Of fresh wodebind, be such as never were  
To love untrue, in word, in thought, ne dede;  
But ay stedfast; ne for plesance ne fere,  
Tho that they shulde hir hertes all to tere,  
Woud never flit, but ever were stedfast.”

It is probable that the common English name of honeysuckle is derived from the facility with which children draw forth its trumpet-shaped corolla from the calyx, and thus suck the honeyed sweets with which it abounds from the nectary. This part of the plant is so formed as in a great measure to bid defiance to the industrious bee; but the hawkmoth readily extracts the honey from the very bottom of the flower; and as much would still be left to waste in the plant, there are many insects which, by a beautiful natural instinct, perforate the tubes at their base, and thus draw forth the honey in a stream.

The woodbine has a light and elegant air, better calculated to ornament rural groves than the more elaborately finished garden; and a much more suitable climber for the rustic porch than the stately portico. The common honeysuckle will, however, grow in almost any situation. This plant is usually propagated either by layers or cuttings, and September is the best month for planting them.

When we look at the little attention this beautiful climber requires at the hand of man, it must be a great source of regret that it is not planted in greater quantities in the parks and public gardens near the metropolis. We have not even seen it in the Regent's Park, and yet the delightful aroma of its flowers, and the pleasing tints they exhibit, would form a most interesting feature in the shrubberies, as even the bare trunk of a lightning-scathed tree would serve as a support for its pendulous wreaths.

**HONEYWORT** is the *Cerinth* major of Linnæus. They are European annuals and biennials belonging to *Boraginæ*.

**HOOKEERIA** (Smith) is one of our British mosses, so called in honour of Dr. Hooker of Glasgow. A bulbous-stemmed plant was also called *Hookeria* by Salisbury, but is now changed to *Brodiaea grandiflora*.

**HOOPOE** (*Upupa*). A genus of birds, ranged by Cuvier in the tenuirostral family of *Passerina*, and by him restricted to two species, both of them natives of the eastern continent. When the characters of their feet are taken into the account, these birds rank with the anisodactyli, that is, with those that have the toes of unequal length, the middle and exterior ones united at their bases, and the hind one considerably produced. No general conclusion can, however, be drawn from the possession of this species of foot, for, though it may always be regarded as an active and efficient one, it is modified so as to suit many kinds of surfaces. The structure of the feet of these birds is, therefore, now very generally omitted in the descriptions of them, or treated as only a very subordinate matter. The generic characters are: the bill very

long and slender, triangular in the section, compressed, slightly arched; the upper mandible longer than the under; the nostrils oval, basal and lateral, open, and protected by feathers; there are three toes to the front, the middle and outer one united as far as the first joint, and the hind one is rather long, and has the claw quite straight, or nearly so; the wings are of mean length, and rounded, the first quill being shorter than the second and third, and the fifth and sixth the longest in the wing; the tail is composed of ten feathers, all of equal length.

These characters of the bill, the feet, and the organs of flight, are all well made out, and harmonise so much with each other, that they form a ready and perfect key to the haunts, action, and manner of feeding of the birds. The bill is properly an insectivorous bill, intermediate in its form between the bills of the humming-birds and those of the bee-eaters; but the form of the wings, which fits them more for ascent and descent than for turning rapidly so as to catch prey on the wing, confines the birds to a different mode of finding their food. The feet combine the properties of perching and those of walking feet; and, while the union of the two outer toes afford a purchase for walking on soft earth, the production and strength of the hind toe, and the shape of its claw, adapt the bird especially for grassy surfaces. On the ground the hoopoes march with a sort of strut, bearing some resemblance to that of the gallinidæ; and yet they not only perch with great firmness upon low bushes and stumps by the margins of the waters, which form their usual roosting-places when watching for their prey, but they can, upon occasion, cling to perpendicular surfaces, though they have not so much command of themselves there as the creepers. It is worthy of remark, that there is a considerable difference in the kind of action of this foot and the zygodactylic foot, which shows how beautifully each of them is fitted for its particular purpose. The zygodactylic foot, from the complete reversal of the outer toe, which is free to its articulation, in order that it may have this position, is a foot for rest upon vertical surfaces; and therefore, though the motions of these birds on such surfaces are sure, they are very slow. Such a foot as that of the hoopoe is, on the other hand, a rapid foot, but not adapted for adhering to the same part of a vertical surface for any length of time; and hence birds which have it are active in their motions, and do not dig insects or larvæ out of ehinks of trees or other hiding-places, but capture them in the free air, though such long and slender billed ones as the hoopoe can reach that upon which they feed either in thick herbage or at some depth under water.

The hoopoes are also birds of very powerful wing, though their momentary flight is not so rapid, or their power of turning in the air so great, as that of birds which have the wings larger and more narrow and pointed. We must not in all cases estimate the absolute power of a wing by the length and pointedness only; for those circumstances are adaptations to a particular style of flight, and not to flying generally considered; for this last purpose, and when the flight is more transfer from place to place, rather than beating about in the air for food, the broad wing possesses some advantages over the long and narrow one. There is no doubt a limit to this; but there is also a proportion between the length and breadth, which gives the maximum of power in a carrying wing;

and we find in the hoopoe very nearly the greatest advantage of this proportion. And when we advert to the habits of the bird, we cannot fail in being struck with the beauty of this adaptation. It is only for transport from place to place that the hoopoes use their wings; for they feed standing or perching. In transporting themselves, they have two species of flight: the one consisting of short journeys over their feeding grounds, when the character of the season induces them to be resident there; and the other, migration flight, in the course of which they are discursive, and often pass over long distances. The wings are equally adapted for both styles. Their breadth, their roundness, and the co-operation of the powerful fan-shaped tail enable the birds to get up and down with the greatest ease upon their short excursions; while the general power of the wings is equally serviceable on those longer flights which the variation of the seasons render necessary.

The hoopoes are inhabitants of the banks of rivers, chiefly of those rivers which are alternately flooded and low, from the alternation of rain and drought. There they feed upon beetles, and other ground insects, and on the spawn of fishes and reptiles. The number of insects which they capture is very great; so that they render no unimportant services to those countries which they frequent, from their activity; they are necessarily voracious feeders, and their nests are somewhat rank with the remains of their abundant food, as is the case with the bee-eaters, the kingfishers, and most of those birds of powerful wing and frequent flight which haunt the margins of the rivers. As is the case with most, if not all of the section, the hoopoes are very handsome birds, fine in their forms and graceful in their motions. There are only two species of them, one of which ranges for a considerable extent over the tropical and northern parts of the eastern hemisphere, over the southern parts of the same, we believe principally confined to Africa, though it also occurs in the south of Asia.

COMMON HOOPOE (*U. epops*) is a very beautiful bird, measuring about a foot in length, and a foot and a half in the stretch of the wings, and weighing about three ounces. On the upper part it is of a rust colour, or rather of a vinous red, with the wings and tail black, crossed with two white bands on the wing-coverts, and four on the quills; the tail is crossed by a crescent-shaped bar of white; and the crest-feathers, which are orange, tipped with black, formed of two rows, and capable of being erected at the pleasure of the bird, give the bird a handsome appearance; the head, neck, and breast, are brownish red, and the rest of the under parts are whitish, streaked with brown. These birds are very discursive with the seasons; they chiefly winter in Africa, at least in the European longitudes, while in the eastern part they find their way southward to India. In the south of Europe they appear in considerable numbers, generally in small flocks, which arrive in the extreme south about the month of March, but they do not make their way to the middle latitudes until the end of the spring, and they retire again at the close of summer. In Britain they appear only as occasional stragglers, and, from the season at which some of them have been obtained, one would be led to suppose that they are strays, who have lost the proper line of migration, and so cannot find their way back again to the south. Within these few years one was shot in Cornwall in the month of December, which

is more than three months later than the time when the regular migrants depart from central Europe. Their straggling into this country bears some resemblance to that of the bee-eaters, pratincoles, and other birds which belong to the central valley of the eastern continent, much more than to the countries on the shores of the Western Sea. We look for our regular migrant birds in the warmth of summer only, or chiefly, in the southern parts of the country; but such a bird as the hoopoe is just as likely to occur in Caithness as in Cornwall, and in the Orkneys or the Hebrides, as in the isles of the Channel. In the eastern parts of the continent they range much farther to the north on their summer excursions, and are not uncommon in Russia, or even in Siberia. This might, however, be expected; for, though the winters there are exceedingly cold, and the summers of short duration, those short summers are very warm, and the country is thronged with such animals as those upon which the hoopoes feed.

Hoopoes, and also some of the other birds which most resemble them in haunts, habits, and character, are understood to make a sort of perpetual summer of it, unless in the case of such strays as happen to fall upon our winter, by missing the line and time of their migration. In consequence of this, the birds are understood to breed two or three times, or even more frequently, according to circumstances, in the course of the year. The nest is described as being rather miscellaneous in its position, but, true to those migrant birds of the banks of rivers, always in some sort of concealment. It may be in a hollow tree, among the tangled roots near the ground, in a hole of a wall, or a crevice of the rock; and though the female does adapt her labour in building so as slightly to improve the less commodious places, yet she is no very skilful nest-builder; and the extent of her labour usually goes no farther than collecting, first, a few withered leaves, and then a few feathers. The hatch varies much in number, being as many as seven when the situation and season are peculiarly favourable, and not more than two when circumstances are the reverse.

In Egypt and several other parts of Africa the birds frequent the meadows in the close vicinity of human dwellings; but on their northern excursions, they are rather fond of solitary places. In Egypt indeed they are greatly encouraged, from their labours in destroying the insects with which the humid banks of the Nile are infested, and accordingly they are as familiar and have their nests as much intermixed with the dwellings of the people as the common house swallows have with us. The eggs are oblong, of a bluish white colour, and marked with small spots of pale brown. The young have to be fed for a considerable time in the nest, and the feeding of them is rather a laborious occupation for their parents. As is the case with all birds of similar habits, the hoopoes have no song, but they have a sort of three calls; one a hollow booming note thrice repeated without modulation; another a little more musical, but still not modulated, which is the love-song; and a sharp hissing note, which is the sound of alarm. In their low flight they jerk on the wing, flirting the tail at the same time; and when alarmed they erect the crest and spread the tail fanwise. They are very easily tamed, and can be made to remain without confinement if they are properly fed. Their flesh is eaten in the south of Europe, but is not understood to be of much value.

The species of Southern Africa is smaller than that now mentioned, its body is nearly black all over, and its length is only nineteen inches. It occurs in India

Hoopoe.

as well as in Africa; and there are some birds there which seem to connect the hoopoes with the bee-eaters, but their manners are little known.

HOP is the *Humulus lupulus* of Linnæus, a useful and well known British agricultural plant. See HUMULUS.

HORDEUM (Linnæus). *H. vulgare* is the well known barley, one of the most useful of the cereals. The cultivation of barley is one of the principal objects of British agriculture, and is of vast importance to the state as well as to the community at large. A large revenue is derived from the manufacture of the grain into malt, whence is drawn the favourite beverage as well as the destructive spirituous liquors of the people. A fourth or a fifth of every well managed farm of light land is annually sown with this grain, as the straw is an excellent winter fodder for cattle. Heavy clayey soils are not suited to barley, as it can with difficulty be got fine enough for the reception of the seed. March and April are the months for sowing; and when laid in in a proper manner, that is in soil perfectly pulverised, dry, and warm, the crop is ripe in nine or ten weeks. There are several varieties of barley in cultivation; but the flat-eared sort (that is when two opposite ranks of the spike are abortive) is the most esteemed. An average crop is from three to four quarters, or about thirty bushels per acre.

HOREHOUND is the *Marrubium alyssum* of Linnæus. A well known medicinal herb belonging to *Labiatae*. An infusion of the leaves has been found serviceable in chronic catarrh, and humeral asthma, and made into a syrup or confection, or candied with sugar they form a popular remedy for slight coughs; and though not used much professionally, they appear to deserve more attention than they now receive.

HORIA (Fabricius). A genus of exotic coleopterous insects, belonging to the section *Heteromera*, and subsection *Trachelides*, having the jaws pointed at the tip, the claws denticulated, with a long bristle attached beneath each; the antennæ filiform, and the hind legs often very thick. This genus is the type of one of the families into which the *Trachelides* is divided by Latreille. The species are of moderate size: the larvæ, according to a Memoir by Mr. Guilding, in the Linnæan Transactions, destroy those of a large species of carpenter-bee (*Xylocopa*), the female of which

NAT. HIST.—VOL. II.

pierces the trunks of dry dead trees, and then makes her cells. The larvæ of the beetle is also found in the same situations, where it devours the food prepared for the bee-grub, and thus causes the latter to perish.

HORNBEAM is the *Carpinus betulus* of Linnæus, the common hornbeam of British woods, belonging to the natural order *Amentaceæ*. The tree is raised from seed, and is a very striking plant in forest scenery. The timber is much used in the construction of rustic implements of husbandry, especially yokes for cattle, whence its name; its catkins are said to be sometimes fraudulently mixed with hops.

HORNBLLENDE. This mineral forms a very important constituent in the granitic masses which appear to form the giant ribs of our globe. It is of a greenish black colour, and consists of silica and alumina with magnesia. Its peculiar tint is principally derived from oxide of iron, of which it contains from twenty to thirty per cent. Hornblende sometimes passes into mica; and if the component parts of the two bodies be compared by chemical analysis, the principal difference will generally be found to consist in the hornblende containing the largest proportion of iron. Those granitic chains which contain the largest quantities of hornblende, usually split into immense blocks, separated from each other by natural seams, and appearing like the ruins of edifices con-

Hornblende.

structed by a race of Titans. The crystalline character of this mineral is delineated in the above diagrams.

HORNET. The largest Hymenopterous insect found in England, belonging to the section *Aculeata*, sub-section *Diploptera*, of Latreille, and family of the wasps, *Vespidae*, being systematically known by the name of *Vespa crabro*. This insect, of which the females are fourteen lines long and the males and workers eleven, is of a rich red-brown colour, with darker markings upon the thorax; the head and abdomen buff coloured; the basal segment (except the posterior margin), half of the second segment, and a triple series of spots on the following segments, brown. The nest of this insect is in its general construction similar to that of the wasp, although of coarser materials, and the columns supporting the layers of cells much stronger. It is constructed either in the hollows of rotten trees, such as willows, poplars, or old oaks, or in the thatch, or under the eaves of barns, and not unfrequently in timber-yards and other similar situations. It is difficult to obtain a sight of their proceedings whilst building; for if the aperture by which they approach to it be too large, they lessen it with a wall of the same material as their cells are composed of, and which, according to Kirby and Spence, consists of decayed wood, but, according to

C C C

Reaumur, of the bark of the ash-tree gnawed to pieces. With this material, moistened by a viscous fluid which they emit, they construct a kind of fragile pasteboard thicker than that made by the wasp, but at the same time not near so pliant, easily breaking between the fingers, of a buff colour, and not at all shining. If the nest of the hornet should not fill the cavity in which it is commenced, they protect it by a common covering of a single piece, not being composed of a series of distinct layers placed one above another. To compensate, however, for this, the covering is of a much stronger consistence, being about four times as thick as the layer of the wasp nest. Reaumur has figured a nest thus protected, which he found in a cavity in a wall, and which, as well as one described by St. Fargeau, in his work just published upon the Hymenoptera (Suites à Buffon, liv. 14), was attached by a footstalk, and defended at its base by one of these coverings, which considerably resembles in form the paper cone in which grocers lap their moist sugar. Beneath this covering the footstalk is dilated and supports the first layer of cells. The subsequent layers are affixed by means of upright pillars, of which the central one is the strongest. The nest is of a somewhat globular form, and the cells are much fewer in number than in the wasp's nest. This insect devours other flies, especially bees, the honey of which it also steals; it also devours almost any other kind of fresh animal substances which it can obtain, ripe fruit, &c. From the size of the insect its sting is very powerful, and is much to be dreaded.

HORN POPPY is the *Glaucium flavum* of Decandolle. A European herb belonging to *Papaveraceæ*. Some of the species are annuals, others biennial; and are occasionally seen in flower-gardens on account of the curious structure of their flowers.

HORSE (*Equus*). A genus of pachydermatous mammalia, but distinguished from all the rest of the order by having only one toe on the foot fully developed, enlarged, and enclosed in a solid hoof. Hence several naturalists have made a separate order of the horse, under the name of *Solipedes*, or entire footed; under which name the genus is made a separate section by Cuvier in his "Animal Kingdom." Though there is only one toe fully developed in the horse, there are rudiments of two others under the skin, but they make no appearance externally.

The general characters are: six incisive teeth in each jaw, which when the animal is young have their crowns marked with a single furrow of considerable depth. There are six grinders on each side of both jaws, which have their crowns square, and crossed with laminae of enamel. In the upper teeth there is a small disc of enamel on the inner edge. The males have one small canine tooth, and sometimes two, on each side of the upper jaw, but none in the under; and these canines are always wanting in the females. Between the canines and the first grinder there is a large open space. The jaws have much less of a grinding motion than those of oxen and other ruminant animals. The stomach is single, and the intestines very long, and furnished with a cæcum of vast size. The feeding apparatus of these animals is but ill adapted for dividing their food, it is carried into the stomach with comparatively little preparation; and the alimentary apparatus resembles a distilling one more than any thing else, the nutriment of the animal being in many instances only a tincture drawn

from the food, which passes through, in many instances, without much apparent change; and the droppings of horses are not so offensive to the smell as those of any other animal. There is another circumstance which shows the imperfect action of the stomachs of these animals upon their food; and that is the great heat which can be produced by the fermentation which the dung of horses undergoes when it is collected in heaps. This renders it a very important article in the cultivation of many plants which require greater heat than that of the season to force them into growth; and by means of this substance, the people of England and similar countries are enabled to rear melons, and other rich fruits of the sunny lands, in as great perfection as they are raised in their native countries. Nor is the advantage derived from manure furnished by horses confined to the forcing of those exotic plants which minister to luxury; for in every country in which horses are abundant, it tells equally upon all cultivated fields; and while the horse is the grand power employed in agriculture, it also furnishes the grand stimulant to every thing that the field produces. There is no country where horses are so numerous, in proportion to the breadth of the land, as they are in England; and owing to this very circumstance, there is no country where various soils yield so abundant a crop of the food of man, or of that of domestic animals. As an instance of this, we may mention the comparatively small breadth of land which suffices to supply the City of London, and its attached boroughs and surrounding villages, with culinary vegetables. As the thing is actually done, and done in so quiet and systematic a manner as that nobody thinks any thing about it, we are apt to pass the matter unheeded; but if the problem were put in a country where there was no such place as London, "to find green vegetables for a million and a quarter of human beings, (something like the inhabitants of the half of Scotland), concentrated within a circle of five miles radius," the problem would be reckoned absolutely impossible; for even those parts of the country which are most thinly populated, and where, consequently, each individual enjoys the produce of the greatest breadth of land, the people are no where better served with vegetables than they are in this same London; if, indeed, they are served as well. This does not apply to the quantity only, for it is equally true of the quality and of the freshness; while the inhabitants are exempted from all trouble in the growing of these things. Now, it is in a great measure owing to the vast number of horses which are employed in the metropolis that this abundant and excellent supply is obtained; because the quantity of horse-manure, incorporated with the soil of the market gardens, keeps it in a continual state of excitement, and produces all the year round, and more especially in the winter season, a much higher temperature than the earth would naturally have in our climate; so that, with a few simple contrivances of art, vegetation is kept up during the winter; and by a skilful adaptation of plants to seasons, the market gardens are kept in continual crop. Now without dressings, of not only a rich, but of a warm and stimulating nature, it would be quite impossible to do this; and thus, were it not for the horses, the art of those cultivators would be, in a great measure, exerted in vain. Nor is it in the metropolis alone, that this advantage is felt, for it applies to every district of the country;

and, whether they are applied to the purposes of agriculture or not, it may be said that the profitable culture of the ground depends in a great measure upon the abundance of horses; and no inconsiderable portion of the superior fertility and consequent value of the lands, immediately abutting on the principal lines of road, is owing to the number of horses which are necessarily kept for the purposes of travelling along those lines. It becomes, therefore, a question of some importance whether, if rail-roads and steam-carriages should ever be introduced as the principal channels and powers of land-carriage, the country might not thereby sustain a loss in the deterioration of its soil, and the consequent diminution of its agricultural produce, for which no rapidity of communication would compensate; for we need not say, that rapid carriage would be of little avail if there were nothing to carry.

It is indeed a truth at once demonstrative to the eyes of every one who chooses to look fairly at it, that the great triumph which British agriculture has gained over the stubborn opposition of inferior soil and wayward climate, is owing more to the vast multitude of horses in the country, than to almost any other cause. At all events, the co-operating circumstances, such as improved implements and modes of culture, and a better understanding of the nature and character of the seasons, would have been unavailing without this one. Nor are the evidences of the truth of this few or difficult to be obtained. Any one who is old enough to remember when, in the poorer districts of the country (and it makes for the argument that they lingered the longest there), oxen or steers were employed to drag along the clumsy and crawling plough, or the lumbering wain, must also have observed with what strides fertility and improvement of every kind came onward with the introduction of the horse. So marked, indeed, has this been in some districts, that it would almost tempt one to believe that the tread of the solid hoof had something of the fancied power of a magic wand about it; and, that the moment that it comes in sufficient number and repetition, the golden harvest waves richly in the autumnal wind, over slopes which were erewhile clad with nothing but brown heather. In most parts of England, the agriculture is owing chiefly to matters of human arrangement, with which we have, in the mean time, no concern, inferior, in proportion to the natural advantages of the climate, to that of many districts in the northern part of the island; yet the horse was introduced at so early a period that there are scarcely any who remember the state of things under ox cultivation, so as even to be able to contrast it fairly with horse cultivation. But the writer of this article remembers well a pretty extensive district of North Britain, when it was in a great degree, at least, cultivated by oxen. At that time wheat was unknown; and even barley was grown in small quantities, and of the light upland kind, called *bigg* or *bere*, which was feeble in the straw and poor in the ear, and very generally so late in ripening that it was caught standing by the heavy autumnal rains, and sprouted, so that each ear looked like a tuft of grass on the top of the stalk. The only other crop, with the exception perhaps of a little patch of grey field peas, consisted of oats, not unfrequently of the black or bearded kind, in which the quantity of farina is small and dark coloured; the crops of these were often so stunted that when full grown, they did

not cover the clods; and it was not rare to find the little *shocks*, which, though consisting of twelve sheaves, were not bigger than hill sheep, standing bleaching in the fields till Christmas.

Some two dozen or two score years rolled on, bearing the spring-tide of improvement upon their wings; and in process of time the ox disappeared from the plough and the wain, and was served up at the table, while the horse put his gallant shoulder to the labour of the wheel. The consequence is, that at the present time, the farmers of that very district depend mainly on the wheat crops for the payment of their rents, or, in supplement to that, to their barley crops; and the greater part of the oats which they grow is used for the feed of those noble animals which have, in truth, been the main-spring of the whole improvement.

Nor must it be supposed, that the introduction of the horse as a labourer was the means of banishing the ox; for on the other hand, the breed of the cattle has been greatly improved, and their numbers very much multiplied; so that we may say the horse has, to a great extent, been the benefactor of the ox, as well as of the owner of both. And it is easy to see the reason: with ox culture, the quantity of manure for the arable land is comparatively small; and as from the rumination and more complete digestion of the ox, the manure is in a more exhausted state, and does not ferment, give out heat, and act as a stimulant like that of the horse. Horses, in order to work properly, cannot be fed wholly on pastures; and upon a pasture which will support and even fatten cattle, horses would be starved. Besides, unmixed grain and succulent food disorder the bowels of horses, and render them unfit for working. Owing to these circumstances, the horse must be, in great part at least, fed in the stable; and consequently, a great deal of nourishment for the land is accumulated. Not only this, but the use of horses in agriculture renders it necessary to cultivate grasses for animal food, as well as the cereal grasses for the food of man, and the more substantial dry-feed of the horse. Also, the introduction of beans, which, though profitable only in strong land, do not exhaust the strength of that land nearly so much as wheat crops do, follow as part of the system of cultivating the land by means of horses. In short, the great quantity of manure, which, up to a certain point at least, increases the value of the land in a route of geometrical progression, lays the foundation of a vast deal of vegetable cultivation and of animal food. We owe to it not a little of the successful culture of that prince of roots, the potato; and we may be said to owe wholly to it the culture of the turnip, the carrot, and mangel wurzel, which, in proportion to the breadth of land which they occupy, yield a greater quantity, and we may add a better quality of food for animals than any other known plants.

With these, and the cultivated grasses and trefoils, and the amelioration of the land by means of tares and other plants, which may be cut down for green-feed in the summer season, the horse has really brought a mine of wealth about the farm; and he may be said to be a most efficient agent in feeding even the pigs and the poultry.

It is unquestionable that the introduction of animal food for general consumption, and of wheaten-bread in the poorer districts, have followed in the proportion of, and therefore have been produced by the introduction of the horse as the principal labourer; and,

were it consistent with the plan of this work to go fully into the question, we feel convinced that we could prove, in the clearest manner, that the superior conquest of soil and climate which England enjoys above all countries in the world, is owing to the greater number of horses, which find so much food for themselves, as well as for all the other domestic animals, and for man.

The proof of this is not confined to the progressive history of our own country, for we have a sort of inverse proof in the case of some other countries, as, for instance, in that of Poland. There was a time when Poland was the granary of Europe, and at that time Polish horses were celebrated; but, in the many vicissitudes which that unfortunate country has undergone in the close of the last century and the elapsed part of the present one, the circumstances of it have been completely changed. One foe or one friend, or friend and foe both, acting a part equally unfriendly, first drained Poland of its horses, for the supply of those armies to which its hapless fields served as a thoroughfare; and no sooner had this cruel exhaustion taken place, than its agricultural produce became diminished in quantity and altered in kind. Up to that period a very great breadth of Polish land, even under one of the most execrable fiscal systems that ever cursed a section of the human race, was employed in the growth of wheat; and though the produce, acre for acre, was perhaps never anything like what it is in the very best parts of this country, yet it was, upon the whole, abundant, so as to enable a large quantity to be exported. Now, however, the case of Poland is sadly altered. There are no doubt some limited districts in which wheat can still be grown to advantage, but these are the districts which are annually made fat by the impoverishment of the rest of the land, through the agency of the heavy falls of rain, and the flooding of the streams and rivers. But the great breadth of the country is absolutely unfit for wheat, not well adapted for oats, and affords but scanty crops even of rye. In consequence of this, a great portion of the breadth of land has been thrown into sheep pasturage, and considerable amelioration has taken place wherever this has been introduced. This depasturing with sheep will in time bring a healthy sward upon the surface, which will retain the rich portion which the winds and rains sweep and wash away when the surface is naked; and thus the land may, by careful management, be renovated in the course of time. It will take a considerable time, however, before Poland shall again be what it once was. The circumstances of Poland are no doubt peculiar in so far. It is, generally speaking, a light sandy or gravelly soil, chiefly the former; and, although this is the foundation of fertility where the land can be "kept in good heart," yet such a soil is always hungry, and hungry in consequence of that activity which renders it fertile under proper management; so that it will not be till the number of domestic animals, and especially horses, shall be greatly increased, that Poland will again become a rich corn country.

We have taken this view of the utility of the horse in preference to any direct allusion to the use of the animal on the farm, the road, the race-course, or the battle-field, because the use of the horse in all these respects is palpable to every one's observation; and therefore, if we were to enlarge upon any of them, we should be merely stating that which almost every

reader has daily opportunities of observing for himself. We have done it, too, because, at this moment, the question is one of serious interest to all who wish to promote the agriculture of the country. The projects which are before parliament, or in preparation, for establishing railway communications upon all the great thoroughfares, which shall render the use of horses for the carriage of goods and passengers quite unnecessary, are no doubt as legitimate as any other kind of speculations; and though it is probable that the greater number of them will totally consume the funds expended on their construction, without any corresponding advantage to the public, yet it is doubtful whether that ought to be made illegitimate ground of objection to them; for, from the periodical exposure of bubbles of one kind or other which takes place in this country, and after which business becomes generally so much more wholesome than it was before, it really appears that there is in this country a power of producing wealth beyond the wholesome necessity for it, just as there is in some constitutions a disposition and over-production of blood, and that a sort of leechcraft and phlebotomy, by means of which the surplus runs to waste, is as necessary in the one case as in the other. The professional difference of the two cases is, that lawyers, projectors, engineers, persons cunning in making great holes in the earth, and multiplying brickbats without number, are the pecuniary leeches, and fatten on the blood of those whom they "ease," which is not the case with their brethren of the lancet.

Nor need we offer any apology, even to the most fastidious reader, for introducing this subject in our notice of the horse; for, as the horse is far more of a domestic than a wild animal, the most important part of his history is its bearing on the general welfare of society.

The chief objection to the origin of those projects is the incapacity of the parties with whom they originate for judging of the bearing of the project upon the interests of society. We say it with great deference, but it is nevertheless true, that, beyond statute, custom, and authority, lawyers are an exceedingly ignorant class of men, and that they should be so may be said to be a matter of necessity, that is, a necessary result of their education and habits. Their official perfection consists in taking the most narrow and partial view of a case, and concealing all the rest as much as possible; and because of this a good lawyer, that is, one profoundly versed in the small subtleties of law, always makes a very partial and dangerous legislator. It is doubtful whether the matter is improved by the other parties who combine with lawyers in the concocting of such projects, because they belong to a class very properly called schemers, very many of whose members and whose plans are visionary. It should seem, therefore, that it would have been desirable to institute somewhere an inquiry into the effect which the general introduction of railways on the great lines of communication is likely to have upon the number of horses; and, again, what effect this is likely to have upon the agriculture of the country. It is quite clear that no description of railroads can be carried into the details of the localities, and that they cannot be profitably used except on the thoroughfares of great traffic, if indeed they can be so there. Therefore, there must still be cartage and carriage-driving on the byways and country roads, and across the farms; and to all such carriages as are

adapted for any of these a railway must be an effective cutting off of the country from the towns, and of the towns from each other. This is, no doubt, in a great measure an imaginary evil, because it is one which the country will not permit, inasmuch as folks will continue to ride horses and drive carriages from one end of the country to another, despite of all the railroads that can be constructed. It is proper, however, that people generally should have a right understanding of the value of the horse, not merely as a working animal, but in the effect which it has upon the general productiveness and general value of the country; and it would be just as well if, when such a project as a railroad is under consideration by the legislature, some of those who profess so warm a zeal for the interests of agriculture would broach this subject, were it only for the purpose of making it better understood.

Of the genus *Equus* there are not many species—probably not more than four; the horse, properly so called, the ass, the zebra, and the quagga—though there appears to be some varieties of the last. They all resemble each other in the structure of their skeletons and the number and form of their teeth, as well as in their digestive organs, much more than almost any other genus of animals. The chief differences, indeed, upon which the distinctions are founded are external, consisting in the different lengths of the ears, the different character of the hair, more especially that in the mane and tail, the different markings, and the general air and expression. So far as is known, all the species are capable of intermixing so as to produce mules; and those mules are perfect animals, capable of breeding back to the pure blood, though two which are equally distant from the purer blood will not breed with each other. Some remarks on this subject will be found in the article *Ass*; and as we have, in that article, treated as fully of that species as is consistent with our limits, we shall confine the remainder of this article to a brief notice of the remaining species and their leading varieties.

We may, however, observe of the whole genus, that they appear to belong, as natives, to a different state of the earth than that which its present surface now presents. The wild ass, the zebra, the quagga, and also the wild horse of Central Asia, are all found on the margins of the great sandy deserts, or at least in those regions where there is a great breadth of country, which is alternately drenched with rain, and burned with drought; or where, as in Central Asia, the general character is dryness. In all places where they are found natives, they are inhabitants of the plains, and not found on mountains, among rocks, or in close forests; neither do they follow the lines of the great rivers, and the rich savannahs, so much as the ox tribe. Their solid feet enable them to bound lightly along hard pastures and sandy plains; and the comparative swiftness of some of the species, and the power of endurance in the others, fit them for ranging over long distances in search of their food. Accordingly, all those which still occur in what may be considered as in a state of nature, are nomadic, or shift their ground with the seasons. They are also, like all herbivorous animals which thus seasonally shift their ground, gregarious in their habits, and generally found in large flocks or droves, usually living in great harmony with each other, though the males, as happens among most gregarious animals, fight desperate battles with each other in the season heat.

Animals of this genus are so very peculiar in their structure and habits, and differ so little from each other, and have so few points of resemblance to any other genus, that it is not easy to say either what are the others to whom they are most nearly allied, or what kind of country or condition of the world is best suited to them. That it should be a state of the country in which vegetable productions are rather abundant, and dry at one season of the year, we may naturally infer; and it is probable that at one period of the earth's history, they inhabited many places in which they are not now to be found. In some points of their characters they resemble the elephants not a little; but they differ greatly from them in others, and especially in the elegance of their forms, and in what is usually termed animal sagacity. They are far from having the same resources as the dog family; and they do not come into such familiar contact with man as to live in the house with him, to follow his footsteps, and to watch and to be influenced by his very looks. But still there is a wonderful degree of tractability in them, and, when properly taught, there are few animals more attached than a horse is to his rider. And though there is a certain degree of stubbornness in the ass, there is perhaps no animal more completely free from vice, or which endures with even half the patience the very extremes of ill-usage.

Thus, though their history as a portion of wild nature, is exceedingly scanty, it is highly interesting so far as it goes. There is another general point worthy of notice; the fossil bones of horses which are dug up in countries which now contain no horses in a state of nature, have been found in accumulations very similar to those which contain the bones of the extinct elephant, and some others of the extinct pachydermata. This leads us to suppose that those other extinct animals must have been co-inhabitants with the extinct horses; and thus, though the evidence is rather imperfect and shadowy, we get at least a glimmering of light upon which to found a belief that the world has, at one time, in our north-western parts at least, been much more a region of pachydermatous mammalia than it is at the present time. Our belief in this is much strengthened when we look at the vegetable remains which appear to belong to the same period, and compare them with the vegetation of those places which such animals now chiefly inhabit. Those remains consist invariably of vegetables of larger growth and coarser texture than those which at present cover the surface in the same places; and, with the exception of the horse in a domestic state, for we really know very little about wild horses, those pachydermata, which are entirely vegetable in their feeding, feed upon much coarser, or, as we may say, rougher vegetables than any of the mammalia, with the exception perhaps of the beavers, and some others of the rodentia which gnaw sticks. We shall now briefly advert to the species.

THE HORSE (*E. Caballus*). As this is the technical species of the genus to which we have chiefly referred in our general remarks, we do not need to repeat any specific characters; and, indeed, the extremes of the varieties, even in our own country, which we may, perhaps, reckon from the Flanders or dray-horse to the Shetland pony in point of size, and from the same to the racer in point of symmetry, are so numerous, that no single description could be so framed as to include them all; for the better that it applied to one, it would be sure to apply the worse to

another. It is, however, well worthy of remark, and shows the general adaptation of the animal tribes to the use of man, that while the less tractable pachydermata have perished from our temperate regions, the horse has remained, and been taken into the service and favour, and we may also say, the companionship of man.

The horse, as it should seem, is an inhabitant of the eastern continent only; no trace of it having been met with as showing that it existed in any part of America, until it was carried there by the European settlers. But in the wide plains of South America, which resemble in many respects those places of the eastern continent, in which wild horses are still met with, the imported ones have been multiplied till they are, perhaps, more abundant there than in any part of the east. Multitudes of the race are found running wild in various parts of the world; but in very many cases, at least, they seem to have descended from domestic generations; and it requires no great stretch of the imagination to presume, that in no country has the species enjoyed absolute independence and freedom. In the southern parts of Siberia, in the great Mongolian deserts, and among the Kalkas, to the north-west of China, they are frequently met with in large herds roaming at will; and they are also found in the deserts on the banks of the Don; but the last are supposed to have sprung from those horses which were turned loose for want of food by the Russians, whilst they were engaged in the siege of Azoph, during their barbarous conquest of the Tartar states to the northward of the Black Sea, which Russian ferocity and zeal for destruction found an Eden and left a wilderness. There are also numbers of wild horses found at the Cape of Good Hope. These are of small size, and, from the vicious disposition they exhibit at the approach of man, they are reckoned almost untameable; it is probable, however, that those animals which have been described as wild horses in this colony, and in some other parts of Africa south of the desert, are a distinct variety, allied to the quagga, and intermediate between that animal and the horse; for the quagga, like the zebra, is a wild and untractable animal, and has not been brought into a state of regular servitude by man. The wild horses of South America, and of the plains to the northward of Mexico, to which we have already alluded, are descended from the Andalusian breed. They were originally conveyed from Spain by the first conquerors. They are most frequently found in the southern districts of the river Plata, as far as Rio Negro, the country of the Patagonians, and the districts immediately adjoining. In these parts they are met in great numbers, some of the herds amounting to not less than ten thousand animals; and each herd comprising many families, the stallion appropriating as many mares as they can, to all of whom he extends his most especial protection. The most prevailing colour of these animals is black; but there are also a sprinkling of bay and dark brown amongst them. Of all the countries in which the horse is found in a wild state, Arabia produces the most beautiful breed. The animals that are met with in these deserts, though not in such large numbers as are found in some other parts we have alluded to, are of superior symmetry and swiftness. The Arabians are solicitous in catching the wild horse, which by their kindness and attention they are not long in domesticating.

It has been very generally believed, that Arabia

was the original country of the horse; and certain we are that there the greatest care is taken to avoid crossing his breed, that the species may be kept entire.

We shall now notice one or two of the most remarkable breeds of horses which are found in different countries of the world, and also a few of those which are of the greatest name in the British islands; but before we proceed to this we may remark that, in our *plate*, Horses, there are given three remarkable varieties, in order to show the contrast. At the top of the plate there is given the Tartar horse, remarkable for the straightness of the frontal line, the squareness of the nose, the wideness of the nostrils, the beard along the under jaw, the general shagginess of the coat, and the length and quantity of hair in the tail. This appears to be the original horse of eastern Europe, as well as of western Asia northward of the central mountains; for if the figure of its head is compared with those of the horses on the Elgin marbles, or any other Grecian sculptures of undoubted authenticity, there will be found to be a wonderful coincidence: nor are these characters entirely lost in the Shetland pony, shown in the under part of the same plate; and, as we shall afterwards see, there is every reason to believe that this pony found its way to the Shetland Islands through Russia and Scandinavia. In the third variety on the plate, representing a draught or dray-horse, there is a remarkable difference in the outline of the head, which is far more convex than in the other; the body is different, too; for, though larger, it is not nearly so compact, and the animal is less strong in proportion to its size, and far less enduring.

The *Arab* is, in many respects, entitled to take the lead among all the breeds of horses; though it is probably not the most handsome, according to our notions. Its frontal line is straight, or even a little concave; the chest is narrow, and the balance is thrown with great equality upon both sets of extremities. But, the narrow chest, by means of which the fore-legs are brought much closer to each other, though essential to a swift running horse, does not adapt the animal well for draught. In Arabia, and the other countries where this horse is so much esteemed, this is not considered a deficiency, because there the horse is not used for the draught, and goods are conveyed on the backs of camels. The skin of the Arab is very fine, the hair smooth, and the form of the muscles and the positions of the veins under the skin very conspicuous. The joints are particularly well made, and those processes of the bones to which the tendons are attached, are very prominent, and the joints themselves are generally free from any defect. The limbs of Arabian horses are particularly handsome; and they have little or no hair on the fetlock. The common height at the shoulder is, in general, rather more than four feet and a half. The height of horses is, however, usually estimated in hands—a hand being reckoned four inches, or three hands to a foot; so that the usual stature of the Arab is between thirteen and fourteen hands. The pace of these horses is rapid and graceful; they do not perspire much; they last a long time; they can continue travelling at the rate of from fifty to sixty miles a day; and five or six pounds of dourra, or the barley of that country, in the evening, is a sufficient feed for them. When at home in the tent, they are fed with barley-straw, chopped short, which is something like our cut-chaff; but more

rudely prepared. The wind of these horses is particularly good; and they can be pushed at their full speed for a long distance without injury to it. They carry their heads, and also their tails, in a very graceful manner; the position of the latter is often tried to be imitated in this country by means which are equally clumsy and barbarous. As is the case in this country, the horses of Arabia are divided into ignoble and noble—the former being doomed to drudge, while the latter are used for the saddle, highly esteemed, and much attended to by their owners. They call the former by a name which means, “without pedigree;” and the latter another name, which signifies a pedigree, which would be venerated even in the Principality—“Known for two thousand years.” The tradition is, that those horses are descended from the veritable stud of King Solomon, and have not been once crossed or corrupted in the blood since he sat upon the throne in Jerusalem; but, be that as it may, they are unquestionably noble animals, held in great esteem, often of enormous price; and we may suppose that among a people so romantic and so poetical in their language as the Arabs, the most wonderful stories are told concerning them. “If,” says the Arabian story, “you meet one of the faithful in the desert, mounted upon a *Kochlani*, and he shall say ‘God bless you,’ before you can say, ‘and God’s blessing upon you,’ he shall be out of your horizon, for the whirlwind toils after him in vain.”

The utmost attention is paid to the breeding of these horses, that they may not be tainted even by accident. The coitus always takes place in presence of a witness, who remains twenty days afterwards to watch the female. The same witness is also present when the colt is cast, and a regular certificate is made out within the first seven days. If these circumstances are not attended to, and the legitimacy cannot be established by the proper certificate, the marketable value of the horse is greatly diminished, whatever may be his real qualities as an individual; and contrary to the custom which takes place in the rearing, at least of half-bred horses, in many parts of this country, as much attention is paid to purity of blood in the female as in the male. The best horses are understood to be bred by the Bedouins of the north part of Arabia; and, though the horses often fetch an immense price, the genealogy is invariably reckoned from the mother. This is at least one of the reasons why the Arabs are so careful that the noble mares shall not be contaminated by the ignoble horses. It is not possible in all cases to prevent an occurrence of this kind; but when a cross does take place the colt loses caste, and is considered to spring from the father which has no pedigree. On the other hand, an improved cross bred between the noble horses and the ignoble mares is very frequently encouraged; but in order that the progeny in this case may not be confounded with the true blood, it takes the designation of the mother; and how much soever it may be improved, it is still ignoble. The Arabs in many instances breed horses for sale to the people of other nations; and those of the pure blood are more readily and cheaply obtained from the people about the towns than from the tented Arabs of the wilderness; for the latter have a strong affection for their horses, and will hardly part with them at any price. It sometimes happens, however, that there is an unlucky mark upon the horse, which really does no harm except to the superstitious feelings of the owner;

and when it is ascertained that any Arab is in possession of such a horse, it may be had for a small fraction of the price which would otherwise be set on one of the same intrinsic worth. Crossing with Arabian horses improves every other breed of the horse, whatever may be the size and character; and for crosses of this kind the stallion is invariably preferred. This is of some advantage independently of securing, as it is understood to secure, a better progeny; for it leaves the mares in Arabia, where they are much more scrupulously attended to than they would be in almost any other country; and as the increase of the race depends more on the number of mares than on that of horses, the leaving of the former in the country enables many more to be bred. In crossing by an Arabian, or “barb,” as it is sometimes called, as being first introduced into Spain through the states of Barbary, the first progeny always partakes of the good qualities of the Arabian; but if the other branch of the cross is very different from an Arabian in appearance, the form of the progeny is often ungainly in the immediate generation. But, upon a principle which we cannot very well explain, the succeeding generations improve in symmetry, and do not fall off in the spirit and other good qualities of the first cross. Thus a horse may be bred with any fraction of pure blood in him, and render at the same time a spirited and handsome horse for any purpose, except the most rough and heavy ones. We have already said that the essential character of the Arab is not that of a draught horse of any description, and therefore if mere strength of draught be the object it cannot be improved by this species of crossing.

The *Persian horse* is evidently a cross with the Arabian, but in which way or with what breed it is not easy to say. According to our notions, its head is rather handsomer than that of the Arab; and it is a more weighty animal, but it wants the spirit and continuation of exertion which are so characteristic of the other. For short distances, these horses are nearly, if not altogether, as fleet as Arabians, but they have not equal wind. The Persians, however, pay great attention to purity of blood in their best horses; and in former times the horses of this country were much improved by the introduction of some stallions from Persia; and the race, bred by crossing with these, was once greatly celebrated for its swiftness on the turf; though, since the real blood was introduced, our swift horses are vastly superior to what they were then.

The *Turkish horses* resemble the Arabs still more than the Persian ones; and they are used almost solely for the saddle.

The *Barbary horses* appear to be a cross with less Arabian blood than either the Persian or Turkish. They have the line of the head convex, and the chest broader; and thus they are not so well adapted for swift running as the Arabs; but they are showy horses, and understood to be very docile. Their general height is about fourteen hands.

The *Tartar horse* to which we have already alluded appears, from all the accounts we have of it, in the different districts which are inhabited by the various Tartaric hordes. It is, however, very general in central Asia, and in the south-east of European Russia, where the breeds differ a good deal according to the nature of their pasture and food, and the kind of treatment they meet with. Their forehead, as already observed, has still a good deal of the Arabian

straightness of outline; but the shagginess of their coat points them out as natives of northern and central Asia, where this is a common character of very many of the mammalia. Their origin is not exactly known, but the probability is that they are originally the same race as the Arabians, only changed by a difference of climate. In all these varieties they are excellent animals, moderate in their feeding, and almost unwearied in their strength. The horses of the Cossacks, and indeed most of those in northern Europe, keeping to the north of the Baltic, appear to be more or less related to this breed, though, as we come nearer the shores of the Atlantic, they do not appear to be quite so shaggy, at least in their summer clothing.

On the continent of Europe there are considerable differences, those of the south partaking more of the Arab character, and those of the north more of the Tartar. In general, they are of light make, but hardy; though in the flat countries adjoining the North Sea they are very heavy, powerful for temporary efforts, but short-winded, and therefore incapable of prolonged exertion.

We shall now just name one or two of the leading breeds of horses which are found in this country. Of these the first, at least in the sporting world, and in respect of price, is,

*The Race-horse.* The English race-horse, which, though far inferior to the Arab in point of endurance, is perhaps the finest horse in the world for moderate heats, such as those on the common race-grounds in this country. They are called blood-horses; but that does not mean that they are pure Arabian blood, on the other hand they are all crosses with English mares, by which means they get an additional strength of bone, while they get spirit from the other branch of the cross. In order that a racer should be "first blood," as it is called, or the nearest possible to the Arab stock, its original descent should be a cross between a pure Arab and a mare which is the produce of a similar cross; but this is often less attended to than the character of the particular parents; and the pedigrees of these horses are far shorter than those of the horses of Arabia.

*The Hunter* is the English horse which ranks next in blood to the "high-mettled racer." The father of this horse is not an Arab, but one of the first blood; and the mother is one degree further removed from the pure blood than the mother of the race-horse. This horse possesses many excellent qualities, having more bone and power than the race-horse, and also more capacity of continued exertion, though inferior in his speed for a momentary effort. The symmetry of this horse, according to our notions, is perhaps superior to that of the race-horse, because it has a fuller chest, a more concave line in the forehead, and is altogether better filled up and rounded.

*The Roadster* is half a cross, or a whole cross further removed from the true Arabian blood than the hunter; but, according to our common notions of beauty, it is perhaps a more handsome horse, plump, round, and of graceful figure and action. But in consequence of its further removal from the true Arabian type, it is much more liable to be influenced by the character of the mother; and both its beauty and its value depend much more on that branch of its parentage. Hence in the breeding of these horses, and in those further removed from the blood, by which the blood of the male parent is always meant, much greater attention should be paid to the qualities of the brood

mare; and it is owing to want of attention to this particular, that so many of our horses of comparatively low blood are so ragged in their forms and so coarse in their manners.

These are the principal horses employed in these kingdoms for sport and for speed; and in many of them a great degree of size, symmetry, and beauty are combined, both for the carriage of private individuals, and for coaches on the high-roads; the studs for which latter purpose, that are in the hands of first-class coach proprietors, containing, all points considered, some of the finest horses in the world. We shall now mention one or two of the races which are more remarkable for their qualities as work-horses only, or for their small size and great hardihood.

*The Dray-horse.* This is the largest horse which is found in the country. It is a portly animal, and capable of powerful effort for a short time; but it is not a good winded horse, and on that account it is wholly unfit for continued exertion. It is understood that the first importation of this horse was from Zealand—though the females are styled "Flanders' mares," by which name Henry VIII. was pleased to designate Anne of Cleves, one of his royal consorts; and it is said, that allusions have been made to the same epithet in later periods of our history. Horses of this breed are sometimes known by the title of "fen horses;" and though they are like most of the domesticated varieties, liable to break into different colours, and are not unfrequently iron-grey, or even pie-bald, yet the prevailing colour is black. They are more abundant in London than in any other part of the country; and they are chiefly used in brewers' drays and other carriages, where a very heavy load is dragged along with frequent stoppages. They are unwieldy; but, the entire horses especially, have very well-formed necks and ample chests; and, if their great size is taken into account, their forms do not want symmetry. There is a great appearance of power about them, but the reality does not come up quite to the appearance; and they are deficient in spirit. They are, however, very showy animals; and in some parts of the world they are highly prized. They are particularly so by the rulers of the native states of India, who, like other semi-barbarous people, esteem them as the chief element of power; and upon a late occasion, when lieutenant Burnes was sent on a mission to appease the wrath of Runjeet Singh, the sheikh-chief of Lahore, dray-horses were considered as the most acceptable present that could be presented to that personage. In that part of India they are known by the style and title of English elephants; and Runjeet Singh was so much delighted with the ponderous brutes, that he addressed to the British governors of India a letter, expressing his admiration of the animals themselves, and stating that the *sheen* of their ample shoes was so splendid, that the moon had been puzzled as to whether it should or should not enter into competition with them, and venture to shine after their arrival at Lahore.

Some of our own writers upon live-stock have expressed very different sentiments on the subject of these horses. "The breed of grey rats," says Marshall, in his History of Yorkshire, "with which this island has of late years been overrun, are not a greater pest in it than the breed of black fen-horses; at least while cattle remain scarce as they are at present, and while the flesh of horses continues to be rejected as an article of human food." It is to be understood, how-

Calmuc Horse

Shetland Pony

Draught Horse

ever, that Mr. Marshall is speaking of the general economy of the country, and with the view to having common horse-work, in agriculture and conveyance, conducted in the most economical manner, and in accordance with the means of obtaining the greatest supply of all kinds of farm produce, and using it in the most economical manner. In this point of view Mr. Marshall does right; for the dray-horse is a horse fitted only for very particular services; and from the great quantity of food which he consumes, as well as from the shortness of his wind, and the consequent frequency of rest which he needs, he would be the most unprofitable horse that the farmer or the carrier could possibly keep. Even in his appropriate situation, that of a London brewer's dray, he is really almost as much an animal of show as of use; and though the momentary pull that he can take, and his power of starting a heavy load, which power he derives from his weight, are probably greater than those of any other breed, yet for continuance of work he is certainly inferior.

It is understood, however, that crossing between this breed and the "rips," or ragged horses, which are used in the country, and accustomed to stand all weathers, produces a breed possessing part of the weight of the one, and much of the hardihood of the other. The horses employed in drawing coal-waggons and other heavy carriages about the streets of London, where the traction required is great, and requires mass in the horses, and also continues and requires wind, and bone and sinew rather than fulness of flesh, are understood to be about the nearest cross to the dray-horse in this respect; and when we get to the waggon-horses, which ply constantly in slow draught along the roads, and creep on for very long distances without halting, we get a nearer approximation to the common country breed, until at last all traces of the dray-horse are lost, and we come to an animal which can endure all labour, and stand all weathers, but which, at the same time, is by no means handsome, neither is it very effective at a short dead pull. It may be of use to some of our readers to present them with a list of the characters of a first-rate horse for agricultural purposes, as given by Mr. Cunley, in his treatise on live stock. "His head should be as small as the proportion of the animal will admit; his nostrils expanded, and muzzle fine; his eyes cheerful and prominent; his ears small, upright, and placed near together; his neck, rising out from between his shoulders with an easy tapering curve, must join gracefully to the head; his shoulders being well thrown back, must also go into his neck (at what is called the points) unperceived, which perhaps facilitates the going much more than the narrow shoulder; the arm, or fore thigh, should be muscular, and tapering from the shoulder, met with a fine, straight, sinewy, bony leg; the hoof circular and wide at the heel; his chest deep, and full at the girth; his loin or fillets broad and straight, and body round; his hips, or hucks, by no means wide, but quarters long, and tail set on so as to be nearly in the same straight line with the back; his thighs strong and muscular; his legs clean and fine-boned; his leg-bones not round, but what is called lathy, or flat."

There are several breeds of named horses, which are conspicuous for their superior usefulness in harness, either as coach horses or for farm-work, among which we may notice

The *Cleveland Bays*. These are, perhaps, the

most handsome working-horses in England, and, indeed, in the world; though it is alleged that of late years they have fallen off. When pure they contain a certain fraction of the blood of the race-horse in them, and, by necessary consequence, some of that of the Arab; but they are strong and hardy, as well as exceedingly active. A pair of them are heavy enough for drawing a two-horse plough in all but the very stiffest lands; and as they step well out, they turn the furrow with more rapidity than almost any other horses; while their wind is excellent, they can continue long at work, and their keep is not very expensive. In ordinary draught, three of them have been known to pull a ton and a half over sixty miles' distance in the twenty-four hours, without requiring any rest except three moderate feeds in the course of the journey. In the plough, the labour of a pair, on the average, for continuance of days, is about an acre a day, which occupies nine hours, in two *yokings*, morning and evening, with a rest at mid-day; and substantial food, of which the quantity requires to be smaller than if the quality were inferior, is by far the most economical, as upon such food the horses will do more work with less fatigue, keep their health better, and last much longer. It may not be amiss to mention, that the entire length of furrow in one acre is rather more than eleven miles and a half, so that they pull the plough along, and turn the furrow at the rate of more than a mile and a quarter in the hour, or, making allowance for turnings, about a mile and a half at full swing; and if the land is free and light, an excellent pair, with a clever ploughman, will "slice away" at the rate of two miles an hour; and with such horses, and a swing plough of the best construction, the same quality of land may be turned in finer style, at less than half the expense that it can be turned by the team of "ragged-rips," and the lumbering wheel-plough, which is used in too many parts of the country. Every one who employs horses in working, ought to know that the greater the number employed to any one draught, the greater the loss of power upon each horse, because it is impossible for any training to make them all pull together; and if the number is above five or six, or even as many, it is perhaps not too much to say, that the entire labour of one horse is lost. In those clumsy teams, too, which crawl like snails along the road or the furrow, there is a great mechanical disadvantage, which is avoided by more light and lively working. Every one knows that much greater power is required to start any motion, than to keep it up after it is started; and as they creep along, the whole may be said to be a succession of starts, and these starts, in a great measure governed, by individual efforts.

On the other hand, when a well-matched pair move onward, keeping step as truly as a file of grenadiers, both shoulders are constantly at their bearing, the plough or the wheel acquires a momentum; and so little do the horses feel it, if they be well chosen and properly attended to, that they will do equal work to four of the others, without a turned hair at the end of it. Nor is the beauty of this superior style of ploughing by any means to be overlooked; for if the work is elegant, a portion of the elegance will be imparted both to the workman and the looker-on. Where the land is laid out in breadth, with belts of planting between, hills rising beyond, and the fertilizing river sweeping, or the sea breaking in gentle ripples to the

fresh morning air, at the bottom of the slope; and where it is the custom to squad the ploughs so that they move along in an oblique line, the one a little behind the other, as regular as the divisions of an army marching in *echelon*, there is not a finer sight in the whole compass of human occupation, or in all the countless charms of a country which combines the grand elements of peace, plenty, power, and worth: and upon such occasions, the well-tuned whistle of the ploughman, which is such favourite music in the ears of the horses, has more natural, and more moral melody, than all the instruments that ever were played in an orchestra.

The different coach-horses used on the roads are generally of this breed, though with a little more blood, and therefore a little lighter than those which are most efficient for agricultural purposes, and other operations of comparatively slow draught. The fast coaches have horses still lighter, and of course with still more blood. They approach in many respects to the hunter; but when the spirit and speed can be found combined with a good deal of bone and strength, the combination produces a coach-horse of the very first quality. This race of horses is purely English in its breeding; and though many of them have been exported of late years, especially to France, they are nowhere found in such perfection as in their native country; this is no doubt partly owing to the superiority of the roads, and partly to the better management of the horses.

The *Suffolk Punch* is a most excellent horse for agricultural purposes, and it is very much used, not only in the county after which it is named, but in other parts of the country. It is rather short in its dimensions, and it wants the elegant gait, and some of the beauty of form, which characterise the better varieties of the breed last mentioned; but it is remarkably compact, firm, and strong, and good winded, so that it can continue a long time at work. Suffolk punches will perhaps do as much agricultural work in a day as any horses which are employed in agriculture, and will continue it for as many days in succession, but they will require a longer time each day. We must again refer to Culley for a description of this very excellent and valuable breed of horses. "Their colour is mostly yellowish or sorrel, with a white ratch or blaze on their faces; the head large, ears wide, muzzle coarse, fore-end low, back long, but very straight, sides flat, shoulders too far forward, hind quarters middling, but rather high about the hips, legs round and short in the pasterns, deep-bellied and full in the flank. Here, perhaps, lies much of the merit of these horses; for we know, from observation and experience, that all deep-bellied horses carry their food long, and, consequently, are enabled to stand longer and harder days' works. However, certain it is that those horses do perform surprising days' works. It is well known that Suffolk and Norfolk farmers plough more land in a day than any other people in the island, and these are the kind of horses used everywhere in those districts." These horses are very efficient, not only in Low Suffolk, or the sea-coast district, which is light and sandy, and kept in heart in a great measure by shell marl, which makes a free soil, but also in such parts of High Suffolk, or the stiff clay district, which occupies the central and largest portion of the county. Very much of this portion, however, is laid down in pasture for cows.

The *Clydesdale Horse* is one of the best breeds in Scotland for farming purposes, and has been long in request both in the Lowlands of Scotland and in the north of England. The origin of this breed is very imperfectly known; and though they are called Clydesdale horses, it appears to be more from the markets at which they are purchased lying in that district than from anything else; for they are very generally used, and also bred, in all the western and midland parts of the Lowlands. They are rather larger than the Suffolk punches, have the neck longer, and step more out. The chest is full and broad, the shoulder thick, the blade-bone rising up to the chine, and not sloping so much backwards in its anterior edge as in the fast-going road-horses. The hoof is round and firm, usually black, or of a deep horn colour, and the heels are wide; the back is straight and broad, but not long in proportion to the weight of the horse, which gives real as well as apparent compactness; the hucks do not stand much out, and the space between them and the ribs is short; the tail is firm, and finely supplied with hair, and the buttocks come so close together as to leave a small furrow for it. These horses are of different colours, but the usual ones are black, brown, and grey, the latter being often beautifully dappled. They are not liked, with a full blaze of light in the face; but a small spot in the forehead, called a "bell" in some of the districts, is considered so great a beauty, that it is often at least tried to be produced by artificial means, and the dealers colour it for the market. Those horses are strong, hardy, good tempered; scarcely one of them is restive; and they lay their shoulders fully and fairly to the draught, and perhaps pull better together than any working horses in the kingdom. It is somewhat singular, however, that the district after which they are named is far less famed for its ploughing than for its horses; at least the writer of this article never saw a furrow in Clydesdale that would have passed muster at a ploughing-match on the east side of the island.

Such, in brief outline, are the principal breeds of horses in the more improved and fertile districts of the British islands, though of course there are local varieties without end. There still remain some smaller breeds, more nearly in a state of nature, which deserve notice. One of them is

The *Welsh Horse*, or *Ceffal*, which some suppose to have been an importation by the Romans, and therefore to have a good deal of the blood of the Tartar horse in it. This horse is not large, neither is it handsome, and upon level ground it is not a swift horse. Still, however, it has its good properties. It is exceedingly hardy, patient of fatigue, by no means destitute of spirit, remarkably durable, and, generally speaking, very tractable. Then, it is a very goat upon the rocks, actually preferring them to softer footing; and, be the ascent or the descent ever so steep and rugged, if the rider can maintain his seat, the ceffal is sure to keep its footing; for in this respect, both in firmness of hoof, and in skill in the planting of it, it is little, if at all, inferior to the mules used in the Andes. For cliff-riding, however, the ceffal must be allowed to have completely his own way; for any attempt on the part of the rider to guide him in a pathless place of difficulty would be attended with hazard to both. It is told of a Welsh gentleman, who was in the train of one of the kings of England, mounted on a charger from his native hills, that,

when the king reproached him for being last in at a riding, he replied, "Hur is as coot a shentleman as he pest, but hur cefal is only a shentleman on the rock, and let them try a riding there." For those who require to be much on horseback, superintending workmen, or doing anything else which does not require fast riding, a cefal is worth all the fine horses in the world, both for comfort in the use and for durability; and then, as to footing, one of the true breed will get upon hard stones, if he can, in preference to turf. The Welsh name *Cefal*, like the French name *Cheval*, is obviously derived from, and indeed identical with, the Latin *Caballus*; and this is a strong proof that the horse was introduced into Wales by the Romans. An additional proof of this is found in the fact, that the people of the north of Scotland, who speak a dialect of the same language as the Welsh, do not give the horse any name at all resembling the Latin, but apply different names to it in different parts of the country, clearly showing that it has been introduced into different places by different nations and at different times.

There are many breeds scattered over the wilder districts, in various parts of the mainland of Britain, and also in the isles, which differ considerably from each other, being, in some instances, exceedingly small, scarcely larger than Newfoundland dogs, and in others of considerable size. Some of these are very rugged in their appearance, and others are very handsome; but they all have a great deal of spirit and strength in proportion to their size, and they are remarkably abstemious in their eating. On Exmoor, south of the Bristol Channel, they are found completely in a state of nature; and we believe that, in some instances at least, they are not considered as property. These are generally very handsome little animals, with the legs slender and beautifully formed; and, when properly trained and broke, and rightly used, they are gentle and docile, and not so apt to shy and be skittish as the horses of the north. For very light weights, or very light carriages, when well matched, they are pretty little creatures; and, as the burden of their own flesh which they have to carry is very light, they can do more work, and continue longer at it, than one would suppose, if their size only were considered.

In the south-west of Scotland there is another breed, rather larger than these, but still handsomer in the limbs, and remarkably hardy and sure-footed. They are usually called Galloways, from the district of which they are natives.

In the southern part of the Western Islands, and more especially in the Island of Mull, there is a very fine breed of these small horses; and these have been largely introduced into the mountainous parts of the main-land. These are the Highland horses, properly so called, which have very shaggy coats, and get pot-bellied, when much exposed to the severity of the weather, and scantily supplied with poor food; but with proper treatment, their appearance is very different, and their qualities are superior, while they can live well in places where the large horses of the low-country would starve. They appear to run gradually into smaller and more shaggy breeds, as we get more northward in the islands; and when we get to Shetland we meet with the very small ponies, to which allusion has already been made. They are found, also, in the Faroe Islands, in Iceland, in Norway, and in the upland parts of Sweden; and as

they all have less or more of the character of the Tartar horses and more of it the farther north they are found, we have as clear a proof as such a subject admits of, that they have come originally from that part of the world, and been introduced into the islands on the north and west of Scotland by the Norwegians, when they were in possession of them.

As to the superiority of the breeds, at the two or three points to which we have alluded, there have been various conjectures, even before it was fully ascertained that no breed of domestic animals can be substantially improved without crossing. The Tartar horse, which, we think, circumstances point out as the ancient parent-race of the whole, is rather a thick-legged horse, or at all events the legs are stout; and it is contrary to the whole system of animal economy, that an animal with thick legs should be a very swift goer. We know that the thin legs and speed of our high-breed horses were procured by means of crossings with the Arab; and we know of no other means by which such a change could be brought about. It is, therefore, highly probable, that those handsome horses with thin legs are the progeny of the native mares by Arabian horses, cast ashore from the wreck of different vessels of the Armada; for it is pretty well ascertained that, in the disastrous rout of that vain-glorious equipment round the island of Great Britain, some ships were wrecked on the coast of Mull, others on the coast of Galloway, and there were, probably, others wrecked on the south coast of the Bristol Channel, which would account for the fine limbs of the Exmoor ponies.

Having now taken a short glance at some of the different breeds of horses in the several localities of Western Asia and of Europe, and noticed, more particularly, those of the British Islands, we are now in possession of the elements of at least a very rational theory of the emigration of those most useful and interesting animals. Whence the Britons obtained those horses which they had in their war chariots, during their contests with the Roman invaders, we have no means of ascertaining which are perfectly satisfactory; but as it is well understood that there was a trade between the south of England and the Levant at an earlier period than this; and as there was commercial intercourse between the south of France,—either the present Marseilles, or some town near the same spot,—and the countries both to the east and the south of the Mediterranean, at a period still earlier; it is highly probable that horses might have found their way by those channels into the south of Europe, and as far as South Britain. Indeed, it is difficult to suppose that such was not the case, for if there was a friendly intercourse between two nations, the one of which possessed the horse, and the other did not, it must have followed, almost as a matter of course, that they who were without this animal should stipulate for it as one of the articles of exchange. It does not appear, however, that at this period the horse was generally known, or, indeed, known at all among the Welch mountains; for the Roman name of the horse there, which is general over all the principality, clearly points to the Romans as having introduced it there. Here the question gets a little embarrassed with the question of the human race, in the two parts of South Britain, and would lead us to suppose that, long before the time of the Romans, the low country of England was peopled by a race quite different from the Welch; and

that upon the Saxon invasion, the Britons did not escape to the Welch mountains, any more than, upon the Danish and English invasions, the Scotch lowlanders fled to the highlands. The probability is, that in either case they would have been escaping from Scylla to fall upon Charybdis; but the point, though necessary to be mentioned, and well worthy of investigation, does not properly fall within our present subject.

We are to understand, therefore, that at very early times there was a bringing of horses from the Levant and the adjacent countries into the southern states of Europe; and that those horses were all brought from countries to the southward and the westward of the Caucasus, the mountains of Armenia, and of Asia Minor. So, also, in the gradual migration of the hordes of central Asia, westward into the valley of the Danube, and so into Germany, and along the north of the Carpathian mountains, through Russia and Poland, into Denmark and Scandinavia, there was a migration of Tartar horses, which ultimately found its way as far as the Norwegian *Viking* extended their excursions.

Thus we are to understand that horses were originally imported into Europe by two channels, one in the south and the other in the centre; for though we may suppose that there was something analogous to this on the line of the Danube, yet the connexion between this line and the shores of the North Sea was, at that time, very much, if not altogether, interrupted by the dense forests in the central parts of Germany.

The southern importation, being of a stock of horses from near the country of the Arabs, may be regarded as having partaken a good deal of the Arabian character, while those of the north were more allied to the Tartar breed, as at present found in the south of Russia and in central Asia.

Thus we are brought to at least not more than two original races, one to the south of the mountains which divide Asia in latitude, and the other to the northward of the same.

The characters of those two races, as they now exist in the two countries, beyond which we cannot trace them, may or may not be climatal varieties of one single parent stock: but the probability is that they are. The race of the south are remarkable for beauty and fleetness; and those of the north for strength and protection from cold in the thickened hair with which their bodies are covered, as compared with the others. Now, when we look at other races of animals, we find that the species which are adapted for fleet motion over long distances, and by that means the best fitted for an extended range over deserts but thinly spotted with anything upon which the animals can subsist, or plains which are subject to seasonal periods of barrenness in consequence of the heat of the sun and the dryness of the air, have the legs long and slender; while, on the other hand, those which have to walk among rocks, to climb hills or dwell in rough and miry places, have always the legs much stouter; so that though they do not admit of such rapid motion, yet the animals can stand more firmly upon them, and use the individual foot with more power for a single exertion. This circumstance did not escape the penetrating glance of Burns, the Scottish bard, for he makes use of the expression—

“Muirland rams,  
Wi’ woo’ like gaits, an’ feet like trams.”

He does not, it is true, use the expression with any reference to the point which we wish to establish; but then this makes his evidence all the more valuable. Now these characters of the Muirland sheep, against which the subject of the poem is understood to be cautioning her progeny, which of course mean, “wool as coarse as the hair of goats,” and “feet as thick in proportion as the shafts of a cart,” are the very characters in which the northern, Tartaric, or hill and bog horse differs from the southern, Arabic, or wide and dry pasture one; and if we find this difference between the characters of horses, and a parallel case in the matter of sheep, we perhaps get as near to demonstration as such subjects will admit of, that the thick-legged, strong-bodied, and comparatively slow horses are descended from the Tartar breed, while the clean-limbed, narrow-chested, and fleet horses are all from the south. It is doubtful whether we have in western Europe any breed of horses, comparatively in a state of nature, which can be considered as Arabians, only altered by climate; but there is little doubt that the Shetland pony is the final stage of diminution in the Tartar horse, with the blood pure; and this is confirmed by the resemblance in the shape of the head, and in many points of the character of the two, for the Shetland pony has really more of the peculiar vigour and inexhaustibleness of the eastern horse, than those handsome ponies which are understood to have Arabian blood in them.

The only other point which remains, worthy of much inquiry, is from what origin the great dray horse, usually called the Flanders horse, has been derived. The thick legs, long fetlocks, square chest, and heavy body of this horse, forbid all possibility of relationship between it and the Arabian, and therefore we must have recourse to the other origin. Now the horses of Holstein, and of all the richer parts of Germany and the Netherlands, near the shores of the German Ocean, are of this character; and they are always larger and heavier in proportion as the country is lower and richer in its surface; and if the severity of the climate, and more especially the pooriness of the pasture, could on the one hand reduce the Tartar horse to the small dimensions of the Shetland pony, it is quite natural to suppose that, on the other hand, the opposite kind of feeding might bring it up to the volume of the dray horse. We know that both the Saxons and Danes invaded England and the Lowlands of Scotland from countries where, in part at least, such horses might be expected, from the modifying influence of climate and pasturage alone; and, therefore, while we see the Tartar horse has been carried by the northern route to Ireland, peopling the whole of the north with little hardy ponies; so the Danes and the lower Saxons carried to Britain, and the countries farther to the south, the parent stock of all those working horses of the British Islands, and the adjacent parts of the continent, which are of heavier make than the Welsh cefal, which, as we have said, may be considered as the breed principally introduced by the Romans. The dray horse may be considered the extreme of this breeding in size; and from what we have said of the incapacity of these heavy horses for continued exertion, it is obvious that for general purposes it has been carried beyond the point of maximum value, by more having been lost in time than has been gained in power.

Such is the history of the horse, in brief outline, viewing that animal as an isolated member of animated

nature, and as accompanying man in his migration over different regions, or as spread into places where previously unknown, by the intercourse of one nation with another. But the horse has another, and in so far as we can predicate morality in a creature unendowed with an immortal spirit, a moral history. Many animals live in a state of perhaps more close domestication than the horse does; and the dog especially, being one which in a state of nature requires more art and stratagem for finding his food, is capable of evincing his attachment to his master in a greater variety of ways. The dog will fight for his master, will fawn upon his master, and will watch and defend his master's property, with a fidelity perhaps unequalled by the human race. The horse does not fight of himself, for his nature is the very opposite of pugnacious; the horse does not fawn, for the spirit of the horse is noble; but the horse, if the expression may be used, stands to his rider more in the relation of a companion and equal, than any other animal stands to man. There is, also, in the gratified look, the erected ears, the arching neck, and the subdued and murmuring neigh of the horse, at the sight of that rider with whom he has been long associated, something more touching, or if you will, more poetical, than in the fawning of all the dogs in the world. Then there is no danger which the horse will not brave along with his rider; and on those occasions man very often borrows courage of the spirit of the animal. In the darkness of night, when the traveller knows not his way, and would be incapable of reaching his home, his faithful horse will carry him in safety through the most difficult places; and be the path ever so intricate, and the obstacles ever so many, if the rein is entirely given up to the horse, not a foot of his will slip or be misplaced on the most difficult ground, and not one of the obstacles will he come in contact with. This is a curious point in physiology, but it is as true as it is worthy of admiration. The firm and entire hoof of the horse, even when shod with iron, seems to acquire in the dark a sense of touch equal to the most delicate finger; and though we cannot account for it, every hair upon the skin of the animal appears to be instinct with all the senses necessary for guiding him along, with the same certainty as though it were clear daylight all about him. If the horse and the rider have been long acquainted with each other, and have frequently made nocturnal journeys, it is of no consequence, if the journey is a homeward one, whether the rider pays the slightest attention to the matter or not; for there have been many instances in which an old and trusty horse has carried his rider asleep for a distance of more than twenty miles. There have been also instances of favourite ponies carrying blind musicians from house to house for the purpose of giving lessons; and indeed it would be impossible to enumerate half the instances which are well authenticated, of quiet and slow-going horses finding and keeping the way without any assistance from their riders; and the same applies to horses habitually used in draught.

The case of horses of higher mettle, though not more extraordinary, is more spirit-stirring; and it is impossible not to be struck and pleased with the expression of glee in hunters at the morning muster, and especially at the notes of the horn; and if the chace is long and lagging, the winding of the horn will spirit them up, and they will spring forward as if endowed with new life.

It is in the battle-field, however, that the horse appears in the full grandeur of his character. His neck is clothed with thunder: "the glory of his nostrils is terrible. He paweth in the valley, and rejoiceth in his strength; he goeth out to meet the armed men. He mocketh at fear, and is not affrightened; neither turneth he back from the sword. The quiver rattleth against him, the glittering spear and the shield. He swalloweth the ground with fierceness and rage; neither believeth he that it is the sound of the trumpet. He saith among the sound of the trumpets, Ha, Ha! and he smelleth the battle afar off, the thunder of the captains, and the shouting."

Such is the description of the horse in battle, as given by the great Legislator of the Jews, at least three thousand three hundred and sixty years ago; and even now that the instruments of war have been rendered more powerful and terrific than they were at the time when this description was written, the horse still exults in, and appears to enjoy, the battle-field as much as ever.

The invention of gunpowder has invested the modern battle-field with all the attributes of that thunder which the ancients regarded as being possessed only by the chief of their gods; but even this, after a very little training, has no effect upon the war-horse further than to excite his courage, and make him more brave and bold amid the augmented terrors. Roaring artillery, sheeted flame, curling smoke, gleaming steel, rolling drums, sounding trumpets, and all the sights and the din of the hottest conflict, never affect either the courage or the coolness of the veteran charger. He will bear his rider as willingly up to the cannon's mouth, or to, or even on, the point of the lance, with the same cheerful obedience as if he were riding to a field of the richest pasture; and though beaten back, and smarting with wounds, he will return again and again to the charge; nor will he quit his duty until he has made the final sacrifice, and his bones are gathered to the unseemly heap in which horses and their riders lie promiscuously together. But it is only while there is a rider on his back that the horse continues thus obedient to his duty; for when the ranks are broken, and the riders gone, horses may be seen careering over the field, as if absolutely in quest of new riders to bring them again into action; and it is said that, upon these occasions, the horses rarely, if ever, trample upon the bodies of the wounded or the dead, with which the field is scattered. If a trumpet sound, too, the riderless horse, if not frantic with the agony of wounds, will follow upon the sound, but will turn away again if he finds that the uniform of the party is not like that of his own regiment. If his rider falls, when the horse is at considerable speed, the horse instantly stops, so that an exchange is frequently soon made of a rider who has lost his horse, and a horse that has lost his rider. Veteran horses are rarely, if ever, panic-struck: and though they are, of course, liable to be taken prisoners, they never desert to the enemy. Indeed, though war is a trade which every one must wish to see abolished, except those who remain at home and gratify their ambition, or other lusts, by the hardship and death of their fellow-creatures, yet, as the characters of the horse in battle are all virtuous without the least mixture of vice, his military glory is as spotless as it is great.

Many anecdotes are told of the strong attachment shown by particular horses to particular riders, with

woom they have been long associated. Of these, some are in all probability exaggerated, but still enough remains to show that those animals are capable of strong attachment and warm gratitude for kind usage; and there have been instances in which a reduced and degraded horse, after plying for years at hard drudgery in the streets, has recognised at once his former military associate, and followed him like a dog.

The most remarkable fact of the whole matter, however, is the evident fondness which horses that have been accustomed to it have for the army; and this appears both in their fondness for particular regiments, and in that for all military array, and even military weapons. It is told that, in one of their insurrections in the early part of this century, the Tyrolese captured fifteen horses belonging to the troops sent against them, and mounted them with fifteen of their own men, in order to go out to a fresh rencontre with the same troops; but no sooner did those horses hear the well-known sound of their own trumpet, and recognise the uniform of their own squadron, than they dashed onward at full speed, and in spite of all the efforts of their riders, bore them into the ranks, and delivered them up as prisoners to the squadron. If an old military horse, even when reduced almost to skin and bone, hears the roll of a drum, or the twang of a trumpet, the freshness of his youth appears to come upon him; and if he at the same time gets a sight of men clad in uniform, and drawn up in line, it is no easy matter to prevent him from joining them. Nor does it signify what kind of military they are, as is shown by the following case. Toward the close of last century, about the time when volunteers were first embodied in the different towns, an extensive line of turnpike road was in progress of construction, in a part of the north. The clerk to the trustees upon this line used to send one of his assistants to ride along, occasionally, in order to see that the contractors, who were at work in a great many places, were doing their work properly. The assistant, on these journeys, rode a horse which had for a long time carried a field officer, and, though aged, still possessed a great deal of spirit. One day as he was passing near a town of considerable size, which lay on the line of road, the volunteers were at drill on the common; and the instant that Solus (that was the name of the horse) heard the drum, he leaped the fence, and was speedily at that post in front of the volunteers, which would have been occupied by the commanding officer of a regiment on parade, or at drill; nor could the rider by any means get him off the ground, until the volunteers retired to the town. As long as they kept the field, the horse took the proper place of a commanding officer, in all their manœuvres; and he marched at the head of the corps into the town, prancing in military style, as cleverly as his stiffened legs would allow him, to the great amusement of the volunteers and spectators, and the no small annoyance of the clerk, who did not feel very highly honoured by Solus making a colonel of him against his will.

The *DZIGGITAI* (*E. Hemionus*). This is the wild horse of central Asia; and is not found in any part of the country which slopes to either sea, but chiefly in the elevated and sandy plains which lie to the southward of the Altaian mountains, and the north west of Chinese Tartary. The native name, which it is difficult to spell in our alphabet so as to bring out the

correct sound of the first consonant, means "long ear;" and the specific name, first given to it by Pallas, signifies "half-ass," which is not un-descriptive of its general appearance. This animal is about the size and figure of a mule, only it is more elegantly made. The head is proportionably larger, and more compressed latterly, than that of the domesticated horse. The forehead is straight and flat; the lips, especially the upper one, are capable of a great deal of motion; the chin and borders of the nostrils are furnished with hairs, about two inches long, forming a sort of mustachios, which are of great service to the animal, in preventing the sand from getting into its mouth and nostrils, as it browses the scattered tufts which spot the barren surface of its pastures. The ears are longer than those of the horse; they are pointed, and the animal carries them very gracefully. The neck is more slender than the neck of the horse, and compressed. It is furnished with a mane of soft brown hair. The body is elongated, compressed latterly, and arched in the spine. It stands comparatively very high on its legs; and the hoofs on the feet are black, and sub-conical, evidently fitted for walking on hard and dry surfaces. The tail bears some resemblance to that of a cow, having short hair for the upper half of its length, and a brush of black hair, nine or ten inches long, at the point. The general colour is greyish fawn; but the summer and winter covering differ considerably, the summer being smooth and flat; and the winter, long, loose, and flocculent, like the winter hair of the camel.

It appears that in former times this animal was found in regions where it is not now to be met with. Aristotle mentions it as being found in Syria, and Ælian describes it as an inhabitant of India; but it does not appear that in modern times it has ever been found to the southward of the mountains: it is highly probable that it is this animal, which has been rendered the wild ass by our translators of the Bible; and besides its great fleetness, there is one peculiarity noticed in the Bible, which is almost decisive on the point, that of "snuffing up the wind," in which the *dziggitai* does more frequently, and with greater energy and style, than any other animal whatsoever. It is probably also the swiftest of all animals; for though the horses of the Tartars are fleet and enduring, it is in vain to attempt following this animal, so as to run it down, though mounted on the finest Arabian.

The Tartars do hunt it, however, both for the sake of its flesh, which they prize highly as an article of food; and for its skin, of which they make excellent leather. Their mode of catching it very much resembles the Highland mode of catching wild deer, or the Scandinavian method of hunting bears,—that is, by a "tinchal," or surrounding circle, which is gradually narrowed, until the animals are hemmed in on all sides, without the means of escaping. The only difference is, that the Tartar circle consists of horsemen, while the others, being in countries where horses cannot readily act, are performed on foot. The animals are usually found in troops, consisting of from twenty to thirty, and sometimes as many as a hundred. These troops are headed by a chief, whose duty consists in watching over the interest and safety of the party, and in cases where danger is apprehended, he is ever on the alert to give the signal for retreat. As the chief is ever the foremost to approach the hunter, his temerity often proves fatal to himself; and his fall is invariably followed by a

dispersion of the troop, which affords additional facility for the destruction of the individuals which compose it. The Mongols, the Touguses, and other nations in the vicinity of the Great Desert, esteem the flesh of these animals as delicate food; and, therefore, they hunt them for the purpose of eating their flesh. Though taken when very young, the dziggital has not yet been tamed by these nations, nor does it appear very likely that they will ever be able to do this, for some of the animals have actually killed themselves by the shackles which have bound them, rather than endure the restraint. It is the opinion of Pallas, however, that under proper management, the taming of the dziggital is practicable, and we cannot doubt but that he is correct; for we do not believe that there is any animal on the face of the earth which may not yet be brought to a certain degree of domestication. It would certainly be a most desirable object to have these animals reduced to a state of subjection; for no animals in the world would make better ponies.

The tract of country which these animals inhabit is one which must, from its locality, have very peculiar characters; but it so happens, that it is the portion of Asia, we may almost say of the whole eastern continent, with which we have the least acquaintance; it extends from 70° to 120° east longitude, and the parallel of 45°, or the latitude answering to the south of France, passes nearly through the middle of it. It is bounded every where by mountains, and no river flows out of it to the south or the west; and those which flow to the north and east, flow but very short distances across it. Towards the west it is divided into three portions, by chains of mountains lying south-west and north-east, the little Altai on the north, the great Altai next southward, and the Musart mountains further to the south, and then the mountains of Thibet form its southern boundary. The three divisions of it are between four hundred and five hundred miles each; and the central division, which occupies the whole breadth toward the east, is more than two thousand five hundred miles in length, and at least eight hundred in its greatest breadth. Thus it is a very large country; and though the rivers all rise in the mountains, and descend towards the intervening spaces, where they are in general lost in the sand, or evaporated by the high temperature of a rainless atmosphere, yet it is understood that those level portions form a table land of great elevation, though how many feet above the level of the sea has not been ascertained.

This is, in its physical circumstances, perhaps the most singular country on the face of the globe; and with the exception of vast numbers of burrowing rodentia, which swarm in the northern parts of it, the dziggital is one of its most peculiar and characteristic inhabitants, and seems to be, more than any other animal with which we are acquainted, an inhabitant of the desert, and fitted for its habitation. It is never found in the forests or on the mountains, whether they are rocky or clad with snow, but keeps to the open and thirsty plains upon which there is no vegetation but tufts of herbaceous plants scattered widely apart from each other. Thus, in order to procure a subsistence, it requires that extreme swiftness of foot to which we have alluded; and as the extremes of summer and winter in such a country must be great, the seasonal changes of its coat fit it admirably for enduring them. The season of heat is about the end

of August; and the foals are dropped in the spring, generally only one at a birth; and they are full grown at the age of three years. In consequence of the extreme shyness and fleetness of the animal, as well as of our ignorance of its country, our knowledge of its habits is but limited. It is ascertained, however, that it can travel a hundred miles or upward without tasting water; and also that it can bear hunger for a long time. It is, however, an animal of wild nature only; though from the circumstances that we have mentioned, it is a very interesting one. Some idea may be formed of the energy of its character from the fact, that in the wild mythologies of the hordes which inhabit the borders of those deserts, it is the animal on which the god of fire is supposed to ride—he scorning all others as too slow for his purposes.

This animal must not be confounded with the wild ass of the same part of the world; for the two do not inhabit the same places, the wild ass being nearer the inhabited countries than this animal, and far less swift in its motion. They are at once distinguished by the superior symmetry of this animal, and by the voice. The wild ass brays, while the dziggital neighs, in tones more loud and clear than those of the horse; and as is the case with horses, the different members of the herd of those animals evince a very great attachment for each other; and as their fleetness protects them against all their human foes, they live in the wide solitude of their mountain-encircled deserts, in a state of perfect peace with all the rest of the living world, the members of which, indeed, are few and far between in the places which they inhabit.

THE QUAGGA (*E. Quaccha*) is an African species, and very abundant in the territory of the Cape, where it is found in large herds, especially in the interior of the country; and it is by no means so shy as the species last described, neither is it so fleet. It is also a much smaller animal, not standing above three feet nine inches at the shoulder. Its tail resembles that of the ass, or rather, perhaps, that of the cow, as in the last mentioned species; but it appears to be as nearly allied to the horse as to the ass, though perfectly distinct from both. Its figure is very light, its head and ears small, and its hoofs cylindrical. Its colours are, the head and neck deep blackish brown, streaked with greyish white, the streaks being lengthways on the forehead and temples, crossways on the cheeks, and forming triangles, or rather cheverons, on the space between the eyes and nose. The ground colour of the body is clear brown on the back, becoming paler on the sides, and passing into pure white in the middle of the under part; while in the middle of the upper, there is a dorsal line of black, extending from the tail to the mane, and the mane is black. There are along each side of the neck ten bands of the same whitish colour as those on the temples. Their cry is different from that of both the horse and ass. Some have compared it to the barking of a dog, and the name *quagga* is also understood to be an imitation of it, though the word *couaay* perhaps comes nearer to it.

The quagga bears some resemblance to the domesticated horse in manners as well as in form. It is a spirited little animal, and repels the attacks of such animals as the hyæna, but it is at the same time easily domesticated, and a willing servant, and not weak, considering its size. There have been instances of carriages drawn by quaggas in the neighbourhood of London; and though there has not, perhaps, been so

much attention paid to them as they deserve, they are frequently employed for doing the work of ponies in the Cape colony.

Where that colony is thickly peopled they are not found; and they migrate, quitting the confines of the colony for places farther northward, when the dry season begins to burn up the pasture; and they do not return again until the rainy season has set in, and vegetation again appears upon the *Karoos*. On their pastures, and during their migrations, they keep by themselves, and do not associate with the zebras, which pasture nearly the same grounds, and migrate in nearly the same manner. Indeed all the swifter herbivorous mammalia partake more or less in this migration; and as they are exceedingly numerous, they furnish abundant food to the lions, which often follow them down to the fields of the settlers, committing depredations upon the domestic animals, and not unfrequently carrying off some of the people.

THE ONAGGA, or DAUW (*E. Montanus*), is another African species, which has been confounded with the quagga, and still more frequently with the zebra, though it is perfectly distinct from both in its appearance, and also in its localities. The quagga is never found but on the plains, for which the shape of its hoofs particularly adapt it; while this species is wholly a mountaineer, and seldom descends to the broad pastures. The distinction between it and the zebra will be best given in the words of Mr. Burchall, to whom we are indebted for the first satisfactory account of it as a species. "The hoofs of animals," says he, "destined by nature to inhabit rocky mountains, are, as far as I have observed, of a very different form from those intended for sandy plains; and this form is in itself sufficient to point out the *dauw* as a separate species. The stripes of the skin will answer the purpose equally well, and show at the same time the great affinity and specific distinction of the *ass*, which may be characterised by a single stripe across the shoulders. The quagga has many similar marks on the head and fore part of the body; the zebra is covered with stripes over the head and the whole of the body, but the legs are white; and the wild *paarde* is striped over every part, even down to the feet. The zebra and wild *paarde* may be further distinguished from each other, by the stripes of the former being brown and white, and the brown stripe being double, that is, having a paler stripe within it; while the latter, which may be named *Equus montanus*, is most regularly and beautifully covered with black and white stripes: add to this, the former is never to be found on the mountains, nor the latter on the plains."

Wilde Parde is the name given to this animal by the Dutch settlers at the Cape; *Dauw* is the Hottentot name; and *Onagga* is a sort of imitation of the voice of the animal. It is less in size than the ass; but it is more handsomely shaped than even the zebra. Very little is known respecting its manners, for it is rarely seen in consequence of the difficult character of the places which it inhabits. From the heavy rains which fall in Southern Africa, the water-courses are torn deep into the rocks, so as to form complete interruptions to any thing like a passage among the mountains; and thus it is difficult to obtain those animals alive, and consequently their habits in a state of nature cannot be observed, neither can it be well ascertained to what degree they are susceptible of domestication. As their general form has

still a good deal of resemblance to that of the horse, the probability is that they *might* be domesticated. If this could be done, there is no doubt that from the nature of the ground on which they keep their feet, they would make excellent hill ponies. More must be known of them, however, before we can come to any conclusion respecting their characters.

THE ZEBRA (*E. Zebra*). This species, which is nearly intermediate in character between the horse and the ass, is found in all the warmer parts of Africa, at least from Abyssinia to the southern extremity of the continent; but now, at least, it is most abundant toward the south. It is probable that, in former times, it was found also to the northward of the desert; for it was not unknown to the Romans, but, on the other hand, brought to Rome upon many occasions, though perhaps not till the time of the Emperors. Dion Cassius says that, in one day, the Emperor Caracalla killed an elephant, a rhinoceros, a tiger, and a *hippo-tigris*, or horse-tiger, by which it is understood that the zebra was meant. It is also mentioned that upon another occasion there were brought from the islands of the Erythrean Sea, some horses of the sun, which were coloured like tigers; and there is no doubt that these must also have been zebras. It is also said, that upon certain occasions the kings of ancient Persia used also to sacrifice a horse of the sun, as an expiatory offering of the most important character. This last circumstance does not prove that those horses of the sun were natives of Persia; but rather the reverse, because of the value of the sacrifice of a single one in the year. Diodorus Siculus says that the zebras were brought from the country of the *Troglodytes*, or men who dwelt in caves, which were near neighbours to the men without heads, and the men with only one broad foot, which they could use as a parasol upon occasions; and this country of the *Troglodytes* is understood to have been the country on the African side, from the strait of *Bab-el-mandel* to Cape *Guardafui*, to the eastward, off which the island of Socotra, which is probably the one alluded to in the former statement, is situated. Be that as it may, the accounts are sufficient to show that the zebra was known to the Romans, and also to other nations of antiquity; but that, though they sought after it for its beauty of colour, they were unable to tame it; and that consequently it must have been the same species as the zebra of the present day, which resists every attempt at domestication.

In a state of nature the zebra is rather larger than the ass; and resembles that animal more in form than either the quagga or the onagga. There is, however, a good deal of confusion in the names and descriptions; because all the three were mixed up in the description of the zebra by the older naturalists; the quagga being regarded as the female zebra, and the onagga, which is less than the zebra but more completely striped, as the young male. All the three animals are, however, perfectly distinct; and the zebra, notwithstanding the beauty of its markings, has no claim whatever to the known mildness of the quagga, or the presumed mildness of the mountain species. We shall quote a small portion of Buffon's description of this animal, in order to show with what caution the writings of naturalists of that period ought to be received. The passage is short, but so circumstantial that one would think the author must have been acquainted with zebras during the whole of his lifetime; and yet the accounts of the three-striped

animals of Southern Africa are all blended in it with most perfect confusion. "The zebra," says Buffon, "is perhaps of all quadrupeds the best made, and the most beautifully clad by the hand of nature. To the figure and graces of the horse, it adds the light elegance of the stag, and the black and white bands with which its body is ornamented are arranged with such wonderful symmetry that we might almost be disposed to imagine that rule and compass had been employed in their formation. These alternate bands are narrow, parallel, and exactly separated; they extend not only over the body, but the head, thighs, and legs, and even over the ears and tail. They follow so exactly the contours of the different parts, enlarging more or less according to the development of the muscles, and the roundness of the different forms, that they exhibit the entire figure in the most advantageous point of view. In the female, these bands are alternately black and white; in the male they are black and yellow, but always of a lively and brilliant tint. They also rest upon a ground of short, fine, and copious hairs, whose lustre considerably augments the general beauty of the colours."

These markings are: the ground colour milk or cream white, with a slight tinge of pale buff or rust colour; but this ground is not absolutely constant in the different individuals. The stripes are black, or blackish brown, running crossways on the body and limbs and down the face. The tail is of moderate length; round in its section, rather slender, marked with a few rings of black or brown, and ending in a brush of hairs of the same colour. Their voice is different from that of all the other species of the genus, being a sort of whizzing or booming sound broken into short lengths.

In their native plains, zebras assemble in large herds, and add much to the interest of places whose character is otherwise both tame and dreary. They are still found in several districts within the Cape colony, but they appear to be more numerous farther into the interior.

The Hottentots and Bushmen of Southern Africa hunt the zebra with great assiduity, in order to feed on its flesh, which they esteem a dainty; and the skin, besides its beauty, is firm and compact, and used for many domestic purposes. The zebra, though much hunted, is not a very timid animal; but it is of rather unsteady temper, and very prone to biting and kicking. Hitherto there has not, we believe, been any instance of its complete subjugation to such a degree as that its obedience could be depended on for any length of time; though there have been many instances in which one that had been long accustomed to the society of human beings allowed certain liberties to be taken with it. There was one in the Tower of London which would suffer a boy to be set on its back, without either biting or kicking; and it was sometimes in the habit of going to the Canteen for a draught of ale, a beverage of which all the horse tribe are particularly fond. Of those which have been kept in other collections in Europe, some have been comparatively mild, and others mischievous; but we are not aware of any case in which they have been completely trained, or where full confidence could be placed in them. Their heels are generally pretty ready, and they not unfrequently try to get a kick even at those who are giving them their food. It by no means follows, however, that they are untameable, or that they might not, if treated with sufficient skill,

be brought into complete subjection. Their handsome appearance renders this well worthy of a trial; for as the whole race are capable of enduring great changes of climate, there is no doubt that they could in time be brought to bear our winter without any difficulty.

The female zebra is understood to go twelve months with young; and the young ones have the markings, only the brown is much paler. Zebras produce mules both with the horse and the ass; and those produced with the horse are said to partake of some of the docile qualities of that parent, and submit to be driven in harness. It is also said, that in these crossings the markings of the zebra are much more perfectly retained than in the crossings with the ass; and this is highly probable, because the horse is far more prone to break into different colours than the ass; and it is a general law, that that which is most yielding in its own colour as a species takes most readily the colour of another species in the case of a cross. The cross with the ass has but little of the marking of the zebra, and one is mentioned which was produced between a female zebra and a Spanish ass. It continued to suck for a year; but as it grew it gradually lost the resemblance of the mother, and became vicious and mischievous. Its colour was dark grey, with transverse bands on the legs, the shoulders, and the tail. It did not neigh, and, as M. F. Cuvier expresses it, it "loved to wallow in the mire, and attacked all the world with feet and teeth."

Such is a brief outline of the genus horse, in which we have endeavoured to touch upon as many points as appeared to be at all consistent with our limits.

**HORSE-STINGER.** A name improperly given by the ignorant to the insects composing the family *Libellulidae* or dragon flies, a perfectly harmless group of insects.

**HORSE-CHESTNUT.** See *Hippocastaneæ*.

**HORSE-RADISH** is the *Cochlearia armoracea* of Linnæus, a well-known culinary plant, and found wild in many places in England. It belongs to *Cruciferae*.

**HORSE-RADISH. TREE** is the *Moringa pterygosperma* of Decandolle, a common East Indian tree belonging to the order *Leguminosæ*. The roots are used as a condiment like those of horse-radish.

**HORSE-TAIL** is the *Equisetum palustre* of Linnæus, a marsh plant of curious structure belonging to a natural order to which it gives a title, *Equisetaceæ*.

**HOSTA** (Jacquin). A genus of Mexican evergreen shrubs belonging to Linnæus's second class, and to the natural order *Verbenaceæ*. The species are cultivated in our stoves, and succeed well under the ordinary management.

**HOTTONIA** (Linnæus). A small herbaceous plant indigenous to England, belonging to the fifth class of sexual botany, and to the natural order *Primulaceæ*. It is usually found in wet ditches.

**HOUSE-LEEK** is the *Sempervivum tectorum* of Linnæus, a common British plant, frequently seen growing on roofs of houses. It belongs to the *Crasulaceæ*.

**HOUSTONIA** (Linnæus). A genus of North American herbs, belonging to *Rubiaceæ*. The flowers are pretty, and the plants are usually kept in pots or placed in rock-work.

**HOVEA** (R. Brown). A genus of evergreen ornamental shrubs from New Holland. The flowers are diadelphous and belong to *Leguminosæ*. The *H. celsi* and *H. purpurea* are esteemed greenhouse plants,

are grown on light loam and moor-earth, and are propagated by cuttings.

**HOVENIA** (Thunberg). A genus of fruit trees, natives of the eastern parts of Asia, belonging to *Rhamnææ*. Generic character: calyx of five spreading parts; petals alternating with the segments of the calyx and convolute; stamens opposite the petals almost hidden; style simple; stigmas three; peduncle thick and succulent; seed vessel three-berried. The most remarkable part of the structure of the fructification is, the peduncle after the petals are fallen becomes enlarged and succulent, and filled with a sweet red pulp, having somewhat the flavour of a pear, and are esteemed as a fruit in China and Japan.

**HOYA** (R. Brown). A genus of curious fleshy-leaved climbing plants, natives of India and China, and belonging to the natural order *Asclepiadææ*. These plants are easily propagated by cuttings, and are grown on loamy soil, requiring but little water in winter.

**HUMBLE-BEE** (*Bombus*). A genus of social hymenopterous insects, belonging to the section *aculeata* and sub-section *mellifera*, distinguished generally by having the upper lip transverse; the proboscis not so long as the body; the second joint of the labial palpi pointed, having the two terminal joints inserted laterally; the posterior tibiæ terminated by two spines; the body thick and very hairy; and, lastly, by the presence of individuals of the neuter sex, with the social peculiarities necessarily resulting from such circumstances, and to which we have already alluded in our article **BEE**. This is a very well-marked group of insects, as contrasted with some other of the genera of bees; but the investigation of the numerous species of which it is composed is attended with very great difficulty; nor is it possible that many of the doubts, at present existing, can be cleared up until a more minute examination of the nests of the various species has been made, whereby only we shall be enabled to give to each species its own individuals. Huber, Reaumur, and Dahlbom, however, have gone far in enabling us to give a tolerably complete account of their habits. The communities of these insects, which have more the character of a republic than that of the monarchy of the hive bee, are annually dissolved at the approach of winter. At this period the fecundated females hide themselves in the crevices of walls, or trees, or under ground; the males and aged females not having this instinct, perish with cold, so that upon the arrival of the next spring, the former only, which had lain dormant through the rigours of the winter, remain alive; these, being soon actuated by a desire to deposit their eggs, are previously compelled to construct a nest for themselves, the workers being all dead; each bee, therefore, has now separately to seek a fresh abode, to prepare it for the reception of, and to make, a quantity of waxen cells, as well as to get a supply of honey. The situation of the nest depends upon the species; some of them dig to a considerable depth underground (as the *Bombus terrestris*), whilst others select a crevice in a heap of stones (as *Bombus lapidarius*), and others (as the *Bombus muscorum*) place their nest, covered with moss or dried leaves, upon the surface of the ground. In the first of these cases, it is necessary that a narrow passage, a foot or two along, should be made to the chamber in which the nest is made, and for which a mouse's nest, or a mole hole suits admirably. The walls of this retreat, as well as the sides of the pas-

sage, have to be rendered smooth. Those species, whose nests are above ground, select a spot somewhat hollowed out and surrounded by plants, either in the open field, or in hedge-rows, banks, &c.; this spot is then cleared, and a dome of moss raised, the little bundles of which it is formed being successively pushed backwards till they are brought home. The passage leading to this nest is also similarly carpeted.

Nest of humble-bee recently commenced; *a*, covered entrance; *b*, waxen cells in which are placed the eggs; *c*, waxen envelope commenced; *d*, mossy dome commenced.

These are the chief differences which exist amongst the humble bees, which some authors have thence divided into carder bees (*B. muscorum*, &c.), lapidary bees which also use moss (*B. lapidarius*, &c.), and humble bees which do not use moss (*B. terrestris*, &c.) As, however, these bees resemble each other in the remainder of their proceedings, the provisioning and enlarging of the nest, and rearing the young, we have not hesitated to introduce them into a single article. Having thus prepared a nest, and given to its dome a rough inner coating of wax, the female places in the middle of it various irregular masses of brown wax, named by Reaumur, *la pâtée*, and which he compares to truffles. Their hollow centres are destined to hold the eggs and grubs when hatched; and are supplied with pollen paste. Here the larvæ live in societies of five or six individuals, until the period arrives when they are ready to assume the pupa state, at which time they separate, and each spins for itself an oval silken cocoon, attached to each other in a vertical position. Reaumur asserts that these grubs feed upon the wax which forms their lodging; but in the opinion of Huber, the latter merely defends them from outward accidents, the food of the larva consisting in a supply of pollen moistened with honey, which the workers take care to supply from time to time, opening the cells, and again closing them after the young have been fed. It is stated, that when the larva is full grown it reverses its position, and becomes a pupa head downwards; in which position, also, the bee makes its escape out of the cocoon; but Dahlbom states that the insect having remained in the pupa state for five days, and then become a perfect bee, immediately begins to gnaw the inside of its cell, upon hearing which the female, with great instinct, immediately approaches the cell, and gnaws round its outside near to the top, from which labour she does not desist until the cap or upper part of the cell has fallen off, and the bee makes its way out of the hole at the top of the cell. The colours of the hairs of the insect when first disclosed are grey, but they shortly assume their proper colours. When these

cocoons thus become untenanted, they are not allowed to remain useless, but are said to be employed by the bees to hold honey and pollen, the tops being provided with a rim of wax, for which service they are well adapted, their form now being that of an egg with one end broken off. Latreille, however, is inclined to doubt this fact, because these cocoons are of a silken nature, and are asserted by some authors to have the aperture by which the bees have escaped at the bottom end. But we have seen that the latter circumstance is at least refuted by some authors, and the different manner in which these breeding cells are transformed into honey reservoirs has been distinctly noticed; thus some give them an internal coat of wax, which would remove Latreille's other objection, whilst others add at the top of the breeding cell funnel-shaped tubes of wax, whilst others content themselves with merely giving the broken margin a waxy rim. But what appears more strongly to prove that the bees prefer making use of cells thus already at hand, and which require but little pains to render them useful, than to take the trouble of making fresh cells, is the curious fact that they contrive, out of four of such breeding cells, to construct five honey reservoirs in this manner: having built waxy tubes to four adjoining cells, and joined the sides of such tubes to each other, an acute quadrangular space is left in the middle, and this space by having a slight coating of wax given to it is easily transformed into a honey reservoir. Cells, however, thus converted are only found in the months of May and June, in the middle of the lower layer of cells from which the early born neuters are produced; and this is another reason why we are induced to believe this fact of conversion contrary to the opinion of Latreille, since it is evident, from the paucity of inhabitants and the quantity of duty which must at this period devolve upon each, that they would resort to all possible expedients to save labour; and this enables us to account for another circumstance in the history of these insects which has been turned to their disadvantage, but which we cannot help thinking tells the other way. Naturalists have held up the hive bee as exhibiting the perfection of insect instinct, and certainly the inspection of a hive-bee's comb would lead to this conclusion. But this is the work of a perennial association never dissolved, and each constantly employed in perfecting the contents of the hive, whilst the case is quite different with the humble-bee; the interior of its nest is all irregularity, and its young, instead of being separately cradled in a waxy cell, are at first herded together in a general cell. The nest indeed is as ingeniously constructed with its dome of wax and elegant covering of moss as the nest of the bee, although here the community is annually dissolved, and the structure, which we have described, the work of a solitary female, endowed, however, with a far more extensive instinct than the inhabitants of the hive of which the various duties are performed by various sets of individuals selected for such particular purposes.

Previous to the completion of the inner coat of wax, the upper portion of the dome has been observed to be opened, on a fine sun-shiny day, "to the extent of an inch, in order, probably, to forward the hatching of the eggs in the interior, but on the approach of night, this was carefully covered in again. It was remarkable that the opening which we have just mentioned was never used by the bees for either their

entrance or exit from the nest, though they were all at work here, and of course would have found it the readiest and easiest passage. But they invariably made their exit and their entrance through the covert-way or gallery which opens at the bottom of the nest, and in some nests is about a foot long and half an inch wide. This is, no doubt, intended for concealment from field-mice, pole-cats, wasps, and other depredators." —*Insect Architecture*, page 66.

The parent *Bombus*, having thus founded the nest, formed a certain number of cells, and deposited her eggs therein, and seen the birth of some of her offspring, dies. The eggs first deposited produce only neuters, which assist their mother in her labours, but the female afterwards deposits male and female eggs. The females produced from these eggs attain a size larger than the workers, although smaller than the parent. Like the neuters they join in the common works of the nest; and like their parent become fruitful, by impregnation by the males, \*born at the same time as themselves, which are also smaller than those males produced at the end of the summer. It may be asked, whether the development of these females is attributable to peculiar food, as is the case with the royal jelly of the queen bees; but this question, although analogy induces us to answer it in the affirmative, owing to the difficulties of observation of the internal economy of the nests of the *Bombus* is at present undecided, notwithstanding the investigations of various observers; as the humble-bees, unlike the hive-bees, refuse to remain in experimenting boxes or glass cages prepared for their reception, but return to their own quarters, so that we are obliged in making a consecutive series of observations to have recourse to the opening, from time to time, of natural nests, a proceeding of danger, owing to the infuriation and powerful stings of the insects.

The community now increases in proportion to the number of young, middle-sized females; the number of males rapidly augmenting, leading to the supposition that the former only gave birth to these individuals; but at the end of August, several females, varying in number from three to eight, according to St. Fargeau, are produced, which are destined to survive the winter after impregnation, and become the respective foundresses of fresh communities. The males which are their partners are also of larger size than their elder brethren, being born at the same time as the larger females.

The tongue of the humble-bee is organised for the gathering of honey, in the same way as that of the hive-bee, with this difference, that in the former it is furnished, near the tip, with a great number of long hairs, forming a brush, enabling the insect to collect a much greater quantity of honey at a time. On arriving at a flower, the bee unfolds its proboscis, in the manner which we have described in our article *BEE*; and removes with the elongated lobes of its maxillæ, and its labial palpi, the petals and stamens, so as to enable it to insert its tongue into the nectary without obstruction; the nectar, thus gathered, ascends by the œsophagus into the stomach, and is then purified.

It some times, however, happens, that the bee selects a flower having a longer tube than its own

\*Some authors assert that the young small females are born long before the smaller males, and yet deposit eggs which produce only males, from which it would appear, as Huber asserts, that, as in the Aphides, a single impregnation is sufficient for more than a single generation.

proboscis, so that it is not enabled to reach the necessary; but this difficulty does not intimidate the *Bombus*, for, from a series of recent observations, made both in this country and in France, it is certain, that the humble-bee has the instinct to alight upon the base of the flower, gnaw a hole through it with its jaws, and thus extract the honey. When it has taken its fill of this delightful beverage, it returns home, where it has duties to perform; for instead of using the honey thus gathered for its own nourishment, it carefully explores the cells to discover the fitness of them, and then inserting its head and part of its thorax into one of them, it unfolds its tongue, compresses the wings of its body, and disgorges from its mouth the honey, clear and bright. The hairiness of the body of the bee renders the collection of pollen an easy matter, and it is no uncommon thing to see a humble-bee come out of a scarlet poppy, a perfect sweep, entirely covered with the black farina; or out of a holly-hock, with his jacket as white as a miller's: this pollen is afterwards gathered together in lumps and deposited in the pollen plates, upon the posterior tibia, by the assistance of the pollen brushes, the structure of which is similar to those of the hive-bee, only we here observe one of those remarkable and interesting facts, which so amply prove the truth of the saying, "*natura maximè in minimis observanda*." The female hive-bee takes no share in the labours of the hive; they do not possess pollen plates, which would, of course, be useless to them; but the female *Bombi*, which join with the neuters in all the labours of the nest, are like them furnished with pollen plates. And it is owing to this necessity existing for the social good of the community, that the female *Bombi* exhibit none of that savage ferocity towards each other, which we have seen to exist in the queen of the hive against even the nymphs of a supposed rival.

When fully established, a nest generally contains fifty or sixty individuals; but Reaumur counted one hundred and fifty empty cells in one nest; and occasionally, but very rarely, the number of inhabitants are stated to amount to two or even three hundred; and now it is that a division of labour takes place. Some take the duty of increasing the size of the nest, and, for this purpose, unite in bringing moss to the nest, just as we see labourers digging stone from quarries, and wheeling it one by one in barrows for short distances, and then consigning it to the next of their companions. In like manner, a file of bees, sometimes amounting to half-a-dozen, is formed between the nest and the heap of moss, the heads of the bees being turned from the nest, and towards the moss. The bee nearest to the moss seizes and detaches a piece with its jaws, and rolls it into a little bundle with its fore-legs, which it pushes under its belly and passes to the next bee, and so on until it reaches the nest. Others now construct pillars of wax, supporting the columns; others prepare the food and feed the grubs; others see to the neatness of the nest, removing all useless things from its interior; and others go abroad to collect honey and pollen, with which they return loaded, and deposit it in the cells. Some, however, probably males, appear to be less solicitous in working, and more disposed to enjoy themselves with the good things of this life. To use the words of Rusticus, "the humble-bees on a sun-flower are very odd mannered. They get as drunk as Bacchus or Silenus; then they get as sleepy as Morpheus, and cross as Cerberus; if you touch

one, he leans on one side, cocking up the opposite legs into the air, and plays divers other antics, till, with his various trials to show that he is sober and able to fight and defend himself, he sidles, staggers, rolls, and falls to the ground, and there lays on his back till he has slept himself sober."

*Bombus lapidarius*; a, mandible of the male; b, mandible of the female.

It only remains to notice the distinctions by which the sexes of these insects may be known, by persons desirous of observing their economy. The males are of the middle size, but vary in this respect at different periods of the year, as above stated; their jaws are narrow, and terminated by two teeth, and on the outside they are clothed with long hairs; moreover, their colours are occasionally different from the individuals of the other sex. The females are the largest inhabitants of the nests; the foundress bee being also larger than any other female subsequently produced; the jaws in this sex are very broad, and spoon-shaped. The neuters, of which, according to Reaumur, there are two sizes, are either as large as the males, or much smaller; these have the jaws similarly constructed to those of the females, so that it is difficult to distinguish them, except by their size, and it appears to us thence probable, that the description of the larger neuters given by Reaumur is applicable rather to the early produced and smaller females, and which is confirmed by the statement of Huber, that many of the spring *workers* couple with the early summer males, a fact which the organization of the former would necessarily prevent, if, as we must infer, the analogy between the neuter hive, and humble, bee exist in all its circumstances.

It is a curious circumstance, that a group of bees, having all the appearance, and indeed general structural characters of the humble-bees, are destitute, as Mr. Kirby first observed, of any apparatus for carrying masses of wrought pollen upon their hind-legs, "the females and neuters of these apes exhibiting those characters which are peculiar to the males of the rest of the family. I suspect that they nidificate underground." Kirby Mon. Ap. Aug. i. 210. These bees have subsequently been formed into a distinct genus, under the name of *Psithyrus*, St. Farg., and it is now supposed by hymenopterists, that they are parasitic in their habits, in which respect the possession of *neuters* (which have never yet been described in any of the species) would be contrary to nature, and it will be observed that their nidification underground rests only upon the suspicion of Mr. Kirby, expressed more than thirty years ago, but which has never yet been confirmed.

HUMBLE PLANT is the *Mimosa pudica* of Linnæus. The movements of the leaves and leaflets of these vegetables, upon the slightest touch, have always excited attention, but the immediate cause has hitherto baffled all philosophers to explain satisfac-

torily. The leaflets of the *Mimoso sensitiva* collapse when touched, but the entire leaves of the *podica* suddenly drop.

**HUMEA** (Smith). A very elegant plant introduced into Europe from New South Wales. It is a biennial, and belongs to the natural order *Compositae*. It is not the flowers, but the elegantly pendent position of its attenuated branches, which makes the plant so much admired.

**HUMMING-BIRD** (*Trochilus*). A genus, or according to some naturalists, a family of tenuirostral, or slender-billed birds, having the feet anisodactylic, or the two outer toes united at their base, and articulated so as to form in some respects a kind of secondary or supplemental foot, which holds on laterally against the other two toes; while these hold on against each other. Thus the foot takes hold two ways; and the owner of it can run in almost any direction upon the bolls and branches of trees. This is the foot of the creepers which are so well known for the remarkable manner in which they run up and down and round and round the trees in our own forests. But the humming-birds, though they all have this description of foot, have it in less perfection than the creepers, because these feed mostly when using their feet, and the humming-birds are in a great measure wing birds.

They are a most singular genus or group, resembling slightly the nectar suckers of the eastern continent, but still vastly different from them in almost every respect; and different indeed from all known birds. They are the smallest of the feathered tribe, some being not much more than half-an-inch in length; they are the most beautiful in the texture and colours of their plumage; for no matter and no other substance can come up to the richness of their tints, or the glowing brilliancy of their metallic reflections. They are the most active of all known birds, exceeding in this respect even the swifts, they are still more powerfully winged, in proportion to their size, than these are; and there are no birds which have the sternum and the bones which give firmness to the shoulder more finely developed. In fact, the whole of their energy is concentrated upon this part of their organization, and their different styles of flight are all equally vigorous. Suspended in the air, and hovering over a flower, their wings move with so much rapidity that they are not seen, except as gleams of light of different colours, but all radiant, as the beams of the sun take them at those angles at which they give out their different lustres; and while the rapid motion of the wings thus renders them invisible, except as gleams of light playing around the little body of the bird, they make a sound similar to that of the humming produced by the wings of bees and other insects; and it is on account of this, that they get their English name of humming-birds. They can hover about in this way for a considerable time; and this rapid motion of the wings, when hovering, appears to give them an impetus for flight, in like manner as a similar, though slower motion, gives an impetus to eagles and other birds of prey, which stoop with great rapidity through the air. In consequence of the impetus thus given, the humming-birds can in an instant dart from one place to another, upwards, downwards, or laterally, without any apparent effort. When they take longer flights, they do not fly on a level with steady wing, but describe a series of flat arches, each arch appearing as if it were a separate leap in the air.

They are exclusively birds of the American continent, and in the rich and warm districts within the tropics, they swarm as numerous as flies do in summer in the forests of Lapland or Canada. The known species amount to several hundreds; and as their native localities are not easily explored, the unknown species may be very numerous. Individually, they absolutely swarm and people the whole atmosphere with the most brilliant, though minute glories of the living world, which are at the same time in a state of wonderful activity; they are not confined to America, within the tropics, nor to the low and warm parts of the tropical countries; though every where they are more numerous, and in greater variety, in proportion as the place is more warm and fertile. Some, however, are found high upon the table lands, and slopes of the mountains, where the climate is not only temperate, but absolutely cold; others range as far southward as the strait of Magellan, and probably, also, into Terra-del-Fuego, while others again are found to the north of Canada, as high as the fifty-seventh parallel of north latitude; while on the west side of North America they reach to latitudes still higher. Nor must it be supposed, that even in this cold latitude they are at all out of their place or their element; for when Captain King was surveying the coast of the extreme south of America, he found large flocks of humming-birds flying about, apparently at their ease, in the middle of a snow storm.

The texture of their plumage is indeed as worthy of attention as the tints of colour, and the brilliant metallic reflections; for though they are very little birds in all the species, and not larger than humblebees in the most minute one, their plumage is exceedingly compact, and probably forms a better defence against alternations of heat and cold, and of drought and moisture, than that of any other birds whatever. The individual feathers are beautifully formed; and more compactly laid than those of any others, if we except the under parts especially, of those birds which are almost constantly in the water without ever getting wetted. But as it would greatly exceed our limits to describe minutely, or even to enumerate, half or even a tenth of the species, we must observe some method in giving brief, general notices of those parts of the structure which come most into action, and may be considered as most characteristic of the whole genus.

The wings claim our first attention, as they are most continually, and most vigorously in use. Of the birds in our own country they most nearly resemble the wings of the swifts, but they are more curved than these, and the birds can perform more evolutions on the wing. The closed wings generally extend beyond the point of the tail, unless where that organ has produced feathers, which it has in some of the species. The first quill is always the longest in the wing; and the other primary quills shorten gradually to the last one. The secondary quills are generally speaking very short; and the wings are not so much loaded with coverts as they are in most birds. The strength and stiffness of the wing are produced by the structure of the quills themselves. The shafts of these are always very strong and elastic; and in some of the species the basal part of the shaft is so much enlarged, that its diameter nearly equals the breadth of the inner web. There is a sort of curvature in the shaft, too, which, in the case of a violent strain against the air, throws each quill partly under the one

following it, so that all the rest of the quills act, in some sort, as coverts to the first ones. The webs of the quills are very closely set, and so completely hooked together, that while the bends of the shafts make openings, through which the air is admitted when the wing is rising, the descending wing strikes the air as if it were a solid. It is this peculiarity of the wings which enables the birds to work them with so much rapidity, when hovering, and which makes them proceed in those arches to which we formerly alluded, when they are upon long flight. The stroke which is given at the commencement of each arch is too vigorous for merely carrying the bird onward in level flight, and thus there is an ascending motion at the first, something like that of a bullet fired at a small elevation, and no new effort is required until the end of the arch is arrived at, when a similar stroke carries the bird along another.

The tail, in birds of this genus, is generally powerful; and it has all the varieties of termination which can well be imagined. It is pointed, rounded, squared, forked, very broad, and much produced in some of the species, and consists of very few feathers, not more than six, in some of the others. In every species, however, the feathers are of the same firm character as those of the wings, and the tail itself is capable of a good deal of motion. It will be borne in mind that the tail of a bird, though often described as a rudder by which the bird is enabled to wheel and turn in the air, answers a very different purpose, namely, that of ascent and descent; and we shall afterwards see that humming-birds require to use a great deal of this kind of motion.

The bill is, in all the genera, long and slender; but it has always a good deal of the insectivorous character, though not of the character of those bills which are used for catching prey while the bird flies open-mouthed, as is done by the swallow tribe, and the goat-suckers, or nocturnal swallows. In some of the species the portion of the bill toward the point is armed in both mandibles with small teeth sloping backwards; but these do not extend to the extremity of the bill, which is always very sharp pointed, and sometimes curved downwards at the tip of the upper mandible, and slightly upwards at that of the lower one. In almost all the species the upper mandible is sufficiently broad for overlapping, and partially sheathing the under one. The general form of the bill, though always slender, and nearly of an equal thickness throughout, with the exception of the tip, which is usually very sharp and keen, varies considerably. Systematic naturalists have sometimes divided the birds into two sections, those which have the bill straight, and those which have it crooked; but it does not appear that very much useful information can be derived from this division; because we are not acquainted with any peculiarity in the habits of the bird which depends on the straightness or curvature of the bill. Besides, some of them have the bill curved downwards, as most crooked bills are; others have it curved upwards at the point; and others again have it curved a little downwards in the basal part, and then upwards again at the tip. Nor is even this all; for the teeth in the mandibles are found in some of the straight-billed species, and also in some of those with crooked bills; which last circumstance would lead us to believe that both forms are made use of for catching exactly the same kind of food, though probably not for getting at it in the

same kind of places. It really does seem, therefore, that the most rational way of dealing with this different shape of the bill, at least until we shall be better acquainted with the habits of the birds, is to regard it simply as one of the specific characters. It is much the same with those other foundations upon which the genus has been broken down into more minute divisions;—a mode of proceeding which certainly renders the history of the genus a little more intricate, and therefore more perplexing to learners and common readers; but other than this left-handed sort of merit, it appears to possess none. A difference in the form of an organ is a useful distinction, in all cases where we can take the difference of function and purpose in the organ along with us; and there may be cases in which a difference of structure may be an excellent guide to the difference of purpose; but this does not hold in such cases as the one under consideration. If we leave out the distinction of being toothed or not toothed in the edges, the bills of all humming-birds resemble each other in their texture, and in the nature of their cutting edges; and therefore we may naturally enough conclude that the leading work to be done is nearly the same in the case of them all; and that the differences in shape relate to certain variations in the places whence the birds obtain their food; and these can be found only by observation, which has not yet been made; and therefore there is no room for speculation upon the subject.

The tongue of the humming-birds is rather a singular instrument; and it resembles the tongues of woodpeckers more than those of any other birds. It is protrusile and retractile, or can be darted beyond the extremities of the mandibles and drawn back again. This is effected by a muscular apparatus not very different from that which gives the same kind of action to the tongue of the woodpeckers. It should seem also that, in some cases at least, the tongue is furnished with barbs very similar to those in the woodpeckers. This tongue is described as consisting, in many of the species at least, of two muscular tubes, which are united together for the greater part of their length, but open towards the point of the tongue, and form something resembling a pair of small forceps. The muscular fibres of those hard tubes are placed in a sort of spiral manner, so that when they act, they lessen the diameter of the tube, but increase its length, and this with a degree of rapidity proportional to their number. So that this tongue has not exactly the same texture as the tongue of the woodpecker, nor does it appear that they contain bone and cartilage as that tongue does. It is probable, also (for the point has not been investigated with much care), that the barbels upon the tongue are not composed of so hard a matter.

In no case, however, does it appear that their tongue is, or indeed can be, an instrument of suction; and indeed we know of no animal in which the tongue alone can perform this office; and of no sucker in any animal which is composed of a single piece. Every sucker must act something upon the same principle as a common sucking pump, and, like that, it must have one part in which the vacuum is formed, and another by which it is to be formed. Thus the humming-bird could not suck with the tongue unless the mandibles answered the first of these purposes; and they are not adapted for any such use, but are simply a prehensile instrument, by means of which the food is seized in some in-

stances, while the protrusile tongue, no doubt, seizes it in others; but whether by means of any viscid secretion, as in the tongue of the woodpecker among birds, and in the tongues of many of the insect-eating mammalia and reptiles, has not been ascertained; but it is probable that in those cases where the tongue is forked or formed into a kind of forceps, there may be a prehensile instrument, which assists in catching the food beyond the reach of the mandibles.

Whatever may be the fact with regard to those minor points, and whatever may be the curvature and structure of the vomer, or cutting edges, there is not the least doubt that the bill of the humming-birds is decidedly an insectivorous bill; and that it no more sucks any liquid substance, than the bill of the godwit sucks the ooze and mud which it simply searches for any little animals that may be contained in it. Thus when we come to examine the bills of those very beautiful and highly interesting little birds, the first thing that we are compelled to do is to demolish the whole of that fine structure of poetic fancy which goes about to feed them on the nectar or sweet matter in the bottoms of the flower cups or tubes of those plants among which the birds sport about with so much liveliness and brilliance; and into which they are ever and anon plunging their bills, and their heads and necks up to the very wings. They do not feed upon this nectar, unless, perhaps, they take up a portion of it along with that which constitutes their principal food. But though the birds do not feed directly on any part or product of the flowers, they do so indirectly in many instances; for the land of humming-birds is in an especial manner also the land of insects; and though some of the winged insects are larger than the birds themselves, there are countless thousands of others which are exceedingly minute. Of these a vast number of species are found sporting in the air; while others are on the leaves, and especially in the flowers, with which the forests of America so much abound. The central forests of that country are festooned with an endless number of climbing plants, usually having the flowers, more or less, bell or trumpet-shaped, many of them of large dimensions and of the most splendid colours; and these flower-cups are turned in every imaginable direction, upwards, downwards, or obliquely; and not a few of them have a curvature in the narrow part of the tube. Thus bills which are long and slender, and also which have various kinds of curvature, are required for getting at whatever substances fit for birds' food may happen to be in those tubes; but from the sharp tips of the bill, and the other circumstances connected with these organs which we have mentioned, this food must be something more solid than any sweet liquid that may be contained in such tubes; and we believe that many of them are not very remarkable for their sweetness.

An examination of the deep cups of flowers in this country will help us to what really is to be found in these cups; and when we consider the difference between the one country and the other, and that the air of those places of America literally teems with life down to a minuteness, to which the eye is not able to follow it, we can easily see what it is that the birds seek in those gay blossoms; for it is, and must be, the small insects which take up their abode there.

Humming-birds are, as we have said, exceedingly numerous; and it is a general law in nature, that every production which is native in any locality, is of

value in the economy of the whole in proportion to its abundance. We find the trees and the ground between very amply furnished with birds; and also with mammalia, adapted for keeping down the vast production of larger insects which is found there; and it is natural to suppose that there should be birds fitted for performing the same operation on the flowers which festoon and adorn those mighty forests; nor could we very readily imagine a race of creatures better fitted for the performance of this duty than the humming-birds are; they are light; they are very powerful in the wing; their plumage can hardly be ruffled; and their powers of action are very great. On these accounts they do not prey on any part of the splendid flowers which adorn their haunts, but are on the other hand the most efficient conservators of them that can well be imagined; and as the flowers are in very great variety, as well as in countless numbers, just so are the birds, and their sizes, and the different shapes of their bills; there is no flower of which they have not complete command, at the same time that their powerful wings bear them from place to place without any apparent fatigue. The *Bignoniaceæ*, or trumpet-flower family, are among the plants of which those birds appear to have especial care, and if the reader will turn to the article *BIGNONIACEÆ*, and the plate with the same title, he will form at least some idea of the form of the flowers of which the humming-birds appear to take especial care. Some of these, which are climbers, are plants of great beauty, with very handsome flowers; and they are capable of making their way to the summits of lofty rocks, and the tops of tall trees; and when the side of an opening in a forest, or the face of a rock, is festooned over with them, and the humming-birds are then in all their activity, multitude, and variety; it is not easy to imagine a finer sight. Some of these plants will grow as far to the northward as the middle States of America; and there are some, also, which can be trained on a wall in the open air in this country; but still their head quarters are in the forests of central America, both on the main land and in the islands. In those places, the sun is never far from being directly over head at mid-day, and sometimes it is exactly so; so that if we suppose the face of the forest or precipice to be turned either to the north or to the south, it will have the benefit of the sun from the time of its rising in the morning to that of its setting at night, only the projections of the different festoons will produce a continual variation of light and shade upon it. In this perpetually varying light upon the splendid and beautiful vegetation, the humming-bird can sport on the wing, and pursue the labour for which they are appointed during the live-long day; and their appearance in numbers at such a place makes it appear as if gems of greater brilliancy than those of all the kings of the earth were floating about in wanton mazes through the air.

We need hardly advert a second time to the feet of these birds, because we have already hinted at their general structure. They are, like the feet of the swifts, small and weak, as compared with the organs of flight; but this is true to that system of wise economy, which nature shows throughout all her works, for the feet are seldom used except for the purpose of repose. In this respect there is a considerable difference between them and the feet of the swifts; and there is a corresponding difference between the kind of surface and substance to which

they are applied. Neither of the birds alight much, if at all, upon the ground; but the swift's foot is adapted for clinging to inequalities in the surfaces of stones and walls, and not for perching upon trees, which the swift never does. The foot of the humming-bird is on the other hand decidedly a perching foot, and they always alight and repose upon trees, bushes, or vegetables of some description or other; and it is said that some of them repose suspended by the claws, with the head undermost, which is the position of sleep among some of the climbing birds, and also of the bats and sloths among mammalia.

Small as these birds are, they are exceedingly bold and pugnacious, attacking not only birds many times their own size, but offering battle to man himself, when he ventures to invade their nesting places. If the nest is approached while the female is sitting, she will fly out, and dart across the intruder with great rapidity, and utter the same sort of sound as a bee does when it menaces an attack in passing. If no direct injury is offered to the nest, the female returns to it in a very short time, and does not again quit it until a new movement is made by the observer. They are, indeed, very little afraid either of birds or of the near presence of man, under any circumstances; and they have no great occasion to fear, because when they are strongly excited, their motion on the wing is so rapid, that the small ones especially can hardly be seen. They may be heard, however, for they utter a sort of scream, not very unlike the screech of the swifts, but considerably more shrill and piercing. From the small prey upon which they feed, their sight must be very keen; and as the sight of long billed birds is never so microscopic as that of short billed ones, they probably see at greater distances than at first thought we would be apt to suppose. They are said to aim at the eyes of those birds which they attack; and in this way their attacks must be much more formidable than their size would lead us to believe, because the point of their weapon is exceedingly keen, and they drive onward with so much velocity, that one stroke of it, taking full effect, would be sufficient to quench the sight of an eagle. Their pugnacity is not by any means confined to those birds and other animals from which they apprehend annoyance; for the males, at least those of the same species, fight desperately whenever they meet. On these occasions they appear to be in a state of the greatest excitement, with every muscle of their bodies in the most intense action; and though their combats are carried on in the air only, they seldom give over till one falls to the ground exhausted, wounded, or dead.

The nests of birds which are so numerous, and differ so much from each other, may be supposed to vary considerably in their sizes in proportion to that of the bird; and rather more than half an inch in diameter may be taken as about the smallest. It is always neatly constructed, but the materials vary in different localities, even with the same species. The eggs are of course small, but not so small in proportion to the size of the bird as the eggs of many other genera; the hatches are understood not to be numerous, two and sometimes only one being the number of eggs usually found in the nests; but they breed with a rapidity unknown in the case of almost any other birds, the time of sitting being about ten days, and the young being able to leave the nest in a week after they break the shell. It is not

known, however, whether all the species come forward in the same short time, for the nests of comparatively few have been carefully examined. All that have been examined, have been found placed on trees, bushes, or vegetables of some sort or another, at a considerable elevation above the ground. One instance is mentioned of a humming-bird being taken on her nest in Jamaica, and brought on board ship. She was tame, allowing herself to be fed with honey, and survived until she hatched her two young ones, but died soon after, probably for want of the proper kind of food. The young survived their mother, and they were fed on the same substance as their mother had been, which was then understood to be their proper, and indeed their only food; and perhaps this also may have been the cause why they did not live long after their arrival in England. In those countries, however, in which they are abundant, all attempts at keeping in a domestic state, for any length of time, have completely failed; and it is natural to suppose that such should be the case with birds which, in a state of nature, are inhabitants of the free air; and, at the same time, so very excitable as these little creatures unquestionably are. That they, or at least some of the species of them, can brave the severity of the weather in both extremities of America, we have direct proof; and as some also have been met with very near the line of snow in central America, perfectly at home, and not appearing to feel any inconvenience, we may naturally suppose that they also can bear a climate which is cold all the year round, at least during the night, while the heat of the sun beats strongly during the day, which is perhaps the severest of all climates.

Central America is, however, their proper place; and it seems to be something connected with the character of the vegetation which makes it so. We have evidence of this when we contrast North America with the southern part of South America; for there has been only one or two species of humming-bird observed to the northward of the Gulf of Mexico, or 30° north latitude, while there are a good many not only under the same parallel in South America, but 20° farther to the southward. Now the character of North American vegetation, and also that of the seasons, ceases to be tropical at no great distance northward of the Gulf of Mexico; while in South America the tropical character continues almost, if not altogether, to the very southern extremity. Still, however, we are not in possession of sufficient data for enabling us to determine in a satisfactory manner why this very singular genus of birds is found in the American continent only, and in no other quarter of the world; for though, as we have said, there is some analogy between them and the nectar suckers of the eastern continent, that analogy is very slight, and does not establish a single important character as common to the two races. There is no such energy of character about that bird, or almost indeed about any bird, which is so great in proportion to its size, as that of the humming-birds; and until we go to the insect-tribes, which have internal muscles acting to the greatest possible advantage, to an advantage indeed which cannot be obtained in the muscular structure of any animal possessing an internal skeleton, we have no instance of so great strength accompanying such diminutive size as we find in the humming-birds.

These curious little birds are not more remarkable for the extreme brilliancy of the plumage, than they

# HELMING BIRDS.

are for the singular production of supplemental feathers, not absolutely requisite either for clothing or for flight, which grow from different parts of their bodies, but chiefly from some part or parts of the head or neck. Those feathers growing from the sides of the head, lengthened and stiff, are sometimes so long as to have the appearance of an additional pair of wings, but they are, of course, without any muscles, by which they can be moved to any extent; and thus they can answer no purpose, save that of a parachute in breaking a fall, which, in birds of so little weight, and so powerfully winged, is not very necessary. These feathers are, we believe, found chiefly, if not exclusively, on the males; and the probability is, that in many cases, at least, they are nuptial ornaments, for we find corresponding feathers, though seldom so much developed as some of these appear, upon the males of many other birds about the commencement of the pairing season, which drop off again after that season is over. But as the humming-birds, in tropical countries at least, breed more frequently than almost any other birds, therefore with them the season of love occupies a great part of the year, and they in consequence wear their livery in gorgets, crests, ruffs, or ear-tufts, that is, produced feathers issuing from the ear-coverts; and those feathers, which are generally of some very brilliant colour, are peculiar in their texture and shape, each of them standing out like a thin but compact scale, which is well defined in its margins, and not easily ruffled.

As we can afford only a very brief synopsis, interspersed with one or two descriptions of such species as have been observed and described with the greatest care, we shall follow the sub-division into five sub-genera, or sub-families, merely for the purpose of breaking the enumeration into shorter portions; for the distinctions of those sub-divisions are so perfectly artificial, and unconnected with any well established difference of habit in the birds, that they are of no use in promoting the rational knowledge of them.

**SUB-DIVISION I.—*Trochilus*.** These have the bill very straight, with only the tips of the mandibles slightly bent; the tail of moderate length, and either square or rounded at the extremity. This sub-division is mostly confined to the tropical parts of America, but they occur on the islands to the eastward, and also to the westward of the main land; and one at least has been met with on the Island of Juan Fernandez, which is nearly five hundred miles distant from the shore, and another species has been observed as far to the northward as California.

**SUPERB HUMMING-BIRD (*T. superbus*).** This species inhabits the island of Trinidad, and in all probability the adjacent parts of the country. It is bright blue on the top of the head, brilliant purple red on the throat, bordered with a white margin, from which the colour gradually passes into pale grey on all the under part of the body; while the upper parts are golden green, with rich metallic reflections. The tail is rounded, and has the tip of the exterior feather on each side white. It is seen in the woods, but not very common; and nothing is known of its manners.

**AZURE-CROWNED HUMMING-BIRD (*T. quadricolor*).** This is a very beautiful species, and found chiefly in Brazil, which may be considered as the head quarters of the humming-birds. The total length is about three inches and three-quarters; the bill is very

straight, rather enlarged at the base, and of a bright yellow colour for the greater part of its length, but black at the tip; the upper part of the head is covered with a cap of very brilliant blue, extending from the bill to the neck, and passing in a straight line immediately under the eyes; the upper part of the body is of a brilliant golden green, and the under part, including the under coverts of the tail, pure white; the wings are purplish brown, and very long and falchion shaped; the tail feathers are greenish on their upper surface, and purplish brown on their under, and they are very compact and strong; the tarsi are very short, but the toes are furnished with claws of considerable length. The young birds have the colours much less pure than the adults. It does not appear that the male of this species has produced feathers upon any part during any season.

**WHITE-STRIPED HUMMING-BIRD (*T. mesoleucos*).** This is also a Brazilian species, though it may be found in other parts of South America. The marking from which it gets its name consists of a white stripe extending from the throat, along the middle of the under part; another, which is slightly crescent-shaped, immediately under the eye; and a third, much less defined, on the turn of the wing. It is rather a large and stoutly made species, being between four and five inches in length, of which the bill, which is very straight, occupies between a third and a fourth; the feathers on the head are scale shaped, and of a greenish colour; the throat is purplish red, extending in a point on each side toward the scapulars; the upper part and the sides are subdued golden green, rather more intense on the middle of the back; the quills are purplish brown, with a slight greenish tinge; and the tail feathers, which are large, and form a slight fork at the extremity, are brownish green, with a round white spot near the extremity of each feather. The female resembles the male, except in having the throat and sides of the neck greyish white.

**DUKE OF RIVOLI'S HUMMING-BIRD (*T. Rivoli*).** is a Mexican species, rather smaller than the last mentioned, and having the bill nearly of the same form, but differing greatly in the colours. The top of the head is intense blue; the gorget on the throat emerald green; the general plumage deep golden green, remarkable for its varied tints in different lights; the gorget is separated from the cap on the head by a line of the general colour which passes over the eye, but terminates before it reaches the gape; the wings are very long and falchion shaped; and the tail is very broad and straight at the termination.

**CORA HUMMING-BIRD (*T. Cora*).** A figure of this species is given in No. 3 of the plate HUMMING-BIRDS, from which it will be seen that it is remarkable for the length of the two middle tail feathers, which are longer than the body, being three inches, while that exclusive of the bill is only two; and the bill, which is very slender, is less than half an inch in length. The upper parts are green, the under parts whitish, the gorget brilliant purple red, and the whole plumage remarkable for its lustre. This is a Peruvian species, having been observed on the west side of the Andes, between the city of Lima and the shore of the Pacific.

**DOUBLE-CRESTED HUMMING-BIRD (*T. cornutus*).** This is, perhaps, the most brilliant species of the whole race, gay as many of the others are. It is a Brazilian species, found on the elevated plains to the northward of the mountains westward of Rio, which are so

rich in gold and precious stones. Its bill is straight; the length of the bill and body about two inches, and that of the tail, which is very pointed, as much more. The centre of the forehead is covered with scaly feathers, with very rich metallic reflections of blue and green; and from each side of the head in an oblique line upwards from the eye, there arise six feathers, which incline forward, and form a very peculiar tuft upon each side of the head. The brilliance of those feathers is beyond all possibility of description; for, according to the angle at which the light is reflected from them, they show the colour of every gem and of every metal when highly polished; and the transition from the one to the other of these is so rapid, that it is impossible to say which is the master colour. The gorget is a very rich purple, extending backwards nearly to the middle of the neck, and forming a point in front which is pendent over the breast. The breast, the fore part of the belly, the lower sides of the neck, and the shoulders, are pure white; the lower part of the belly and the upper part from the shoulders are delicate bronze green; the wings, which are very long, are bronze brown, as are also the two central feathers of the tail, but the remaining feathers of the tail are white. The female wants the produced feathers, but has the green on the body fully as brilliant as the male, and the top of the head a most intense blue, behind which there is a patch of green on the nape, separated from the green on the back by pure white. Both birds are very lightly and elegantly formed, and, taking them altogether, it is impossible to imagine creatures possessed of more exquisite and more varying beauties.

**VIOLET-EARED HUMMING-BIRD** (*T. auritus*).—Bright green in the upper part, and pure white in the under, with the exception of the vent feathers, which are greenish. A tuft of produced violet feathers, projecting from the ear covert; a black line from the gap across the eye, the tail wedge-shaped, with the extreme feathers white, and the four centre ones very dark green. The female wants the produced feathers, and has the under part greyish. This species is found generally in the northern parts of South America.

**VIOLET-TUFTED HUMMING-BIRD** (*T. petasophorus*).—This is a Brazilian species, with the general tint of the plumage golden green in various shades, the wings brown, and the under tail coverts white. From the ear coverts there are two tufts of produced feathers which extend downwards and backwards. Their colour in some lights is violet, but in others it is golden green; the female is of a very intense emerald green.

**TUFTED-NECKED HUMMING-BIRD** (*T. ornatus*).—This is a very singular species, especially in the ornamental feathers of the male, which appear in the shape of a large crest covering the whole upper part of the head, and in two tufts of produced feathers originating in the sides of the neck, and in shape and size bearing some resemblance to vines. We believe it is the species marked in the plate HUMMING-BIRDS, by mistake, as *T. auratus*, which should have been the last-mentioned species, save one, and named *auritus*. The male has the crest and produced feathers of bright brownish red, with a circular spot of pure green on the tip of each feather. The throat and breast are brilliant green, surrounded by a margin of chestnut. The upper parts are bronze green, with blue reflections, the under part purplish green immediately below the chestnut border, and passing into a deeper tint on the belly. The rump is greyish white;

the centre feather of the tail greenish, and the lateral ones chestnut red. The female wants the produced feathers, has the gorget pale chestnut, and the tail feathers red crossed by a broad bar of green.

**THE SHIELDED HUMMING-BIRD** (*T. scutatus*) has the forehead and gorget green, with a large tuft of deep blue feathers of a downy consistency, and tipped with yellow at the extremities on each side of the neck. These are not found in the female.

**DELALAND'S HUMMING-BIRD** (*T. Delalandii*). The male of this species is one of the most singular of the whole, especially in the form of its crest, from the centre of which there rises one long and narrow feather of a bright blue colour, and white at the tip. The upper part is bright green, the under part rich blue, the flanks and sides of the neck grey, and there is a white spot composed of two or three scaly feathers over each ear covert. This species is found in Brazil. There is another species found in the same country which resembles this one in the form of the crest on the male, but the colours are different.

**STOKE'S HUMMING-BIRD** (*T. Stokei*). This is, perhaps, one of the most splendid of the whole tribe; and the circumstance of its being found in the remote island of Juan Fernandez, rendered celebrated by the romance of Robinson Crusoe, tends to heighten the interest. If De Foe in forming his romance had been aware of the existence of this splendid little bird, he would have, no doubt, turned it to great advantage. This species is about four inches and a half in length, of which the body and head occupy about two inches. The head is adorned with a crest of scaly feathers, of a rich blue colour, with purple reflections; the whole of the upper part from the nape to the tail coverts is bright emerald green, the feathers scale-shaped, and increasing in size as they approach the tail, where the termination of the coverts is well defined. The tail consists of ten feathers, which are long and remarkably strong in proportion to the size of the bird; the two middle ones are wholly green, the others are green on their outer webs, and white on their inner, except the outer ones, which have only the distal half of the outer web green. A patch under and behind the eye is purple with green reflections, and dotted over with circular spots of metallic lustre, which are variable from pale pink to deep violet, as the light is differently reflected. The under part is white, with a greenish tinge on the chin, and marked all over with eye-shaped spots of bright emerald green. Altogether the plumage of this bird is exceedingly rich.

**VIOLET-CROWNED HUMMING-BIRD** (*T. sephanodes*). This is a migrant species in South America, at least in the southern parts. It is about four inches long, rather compactly made; has the bill straight; a flat purple crest on the head; the upper part golden green; the under part yellow on the throat, white on the sides of the neck, and reddish white on the breast and belly. The feathers on the fore neck and breast are scale-shaped, and each of them is marked with a circular brown spot. These birds, though migrant in Chili, are described as being very hardy.

**RUBY-CRESTED HUMMING-BIRD** (*T. moschitus*). This is a very common species; but it is peculiar in its attitude, and its colouring is exceedingly rich, and varies greatly in different lights. It is between three and four inches in length, but stoutly made, and has the bill long and strong. There is no produced crest, but the feathers on the upper part of the head to the nape, and also those on the under part of the body

and sides of the neck, are scale-shaped, and remarkable for the countless number of tints which they display. The top of the head and neck are well defined in their contrast with the adjoining plumage; but it is difficult to say what is the real colour; when the light is simply reflected, the colour is dull reddish brown; when it falls a little slantingly, so as to produce refraction, the lustre becomes metallic; and when the light falls so obliquely as to bring out the full reflection, the colour is rich ruby red, and the lustre not inferior to that of the gem. The scaly feathers on the throat and breast are dull greenish brown by simple reflection; but different refractions bring them up through every tint of golden green to a fine topaz yellow. The remaining parts are rich brown, except the vent feathers, which are white. The wings are purplish brown with faint reflections of green; and the tail, which is very large and strong, and capable of very extended and rapid motion, is delicate reddish brown, with a dark crescent-shaped border on the extremity of each feather. This species is very generally distributed, being found in almost all the West-India islands, and also generally over the continental part of tropical America. It builds a very neat nest, constructed of small bits of lichen externally, and neatly lined with vegetable down. The female differs considerably from the male. It is small, and bright golden green above, with the two middle feathers of the tail bronze green, and a bar of the same on the other feathers near their basis, while the tips, which in the male are darker than the rest of the feathers, are white in the female. The female also wants the rich scaly feathers, and is greyish brown on the under part.

**MAGNIFICENT HUMMING-BIRD** (*T. magnificus*). The application of superlative names either to birds or to flowers is generally rather an unfortunate matter; for it very frequently happens that after the finest name that can be thought of has been given to one species, another species of far greater beauty is discovered, to which only a common name can be applied. This is the case with the present species of humming-bird, which is much inferior, both in form and in plumage, to many of the others. It is golden green above, the same colour but much less bright on the under part, emerald green on the throat, and gorget, and the crown in the male, which is chestnut for part of its length, and then white with black tips to the feathers. The female is without the crest, and has the gorget chestnut colour. It is a Brazilian species.

**RED-NECKED HUMMING-BIRD** (*T. rufus*). This species is not so brilliant in its general plumage as some of the others; but the colours are finely contrasted, and the shape of the bird is handsome. The cap, which reaches only to the top of the head, and the feathers on the turn of the wings, are green. The general plumage of the body is salmon colour, fading into greyish white on the breast. The gorget of scale-shaped feathers, which extends on each side, of a brilliant cinnamon red, which varies in different lights. The female is greenish in the general plumage, except a few spots of cinnamon colour on the breast.

**GOULD'S HUMMING-BIRD** (*T. Gouldii*). This is a singularly formed and very handsome species, found somewhere in tropical America, but the particular locality is not known. In the form of its body and its ornamental feathers, it resembles the tufted-necked species, which we have already described; but it is

very different in the colours of its plumage. The forehead is green, the crest bright red, of a chestnut tinge, the scaly feathers on the breast very bright green, the wings and external feathers of the tail greyish purple, the back and middle tail feathers golden green, and the under part dark brownish green; the tufts which spring from the sides of the neck are, however, the most singular parts of the plumage. They are large, shaped something like the wings of a butterfly, of a pure white, with the exception of the tips, which terminate in perfectly circular spots of brilliant green. These spots form a border round the under edges of the tufts; and there are a few feathers in front, which are much shorter than those that give shape to the tuft, and unequal in their lengths, so that they form detached green spots upon the white ground of the tuft. This species, as is indeed the case with the greater number, is known only as a museum specimen; but it is presumed to inhabit the same countries as the tufted-necked one, which it resembles in so many respects.

**DUCHESS OF RIVOLI'S HUMMING-BIRD** (*T. Anna*). This species is an inhabitant of California, and has only been known for a few years, while its habits are still unknown to us. It is not quite three inches and a half in length, of which the bill and tail make up nearly one half, so that the body is small. It is a compact little bird, however, and powerfully winged. The most characteristic marking is the cap on the head, which is united to the gorget, with the exception of a black streak extending from the eye forward to the gape. This cap descends toward the nape, is produced in a large lobe on each side of the neck, and scalloped in the lower margin of the throat. It is composed of scale-shaped feathers, small at the base of the bill, but gradually increasing in size to the termination, where each feather forms a scallop. The colour is very rich purple red, changing into various tints in different lights. The upper parts, including the rump and the lesser coverts of the wings, are bright golden green; the wings are purplish brown; and the tail, which is slightly forked, is brown, with the exception of the two middle feathers, which are bronzed green, with bright metallic reflections. The under part is yellowish white immediately below the gorget, passing into greenish grey on the belly, and into whitish on the under tail coverts. Enough of the manners of the bird are not known for enabling us to determine whether it is resident in California all the year round, or only a summer visitant, as the northern humming-bird is in the United States, and the other species, which appear farther north on the west coast of North America, are understood to be.

**GOLDEN-GREEN HUMMING-BIRD** (*T. prasina*). This is a very small species, but it is remarkable for the intensity of its colour, and the energy of its expression. The body and tail are about two inches in length, and the bill is nearly two-thirds of an inch; the wings are long; the tail is stout, and strongly supported by coverts; the crown of the head and the throat and breast are covered with scale-shaped feathers; and there are produced feathers on the sides of the neck, consisting of a pointed row downwards from the eye, and a row of scale feathers from the base of the bill, passing immediately in front of the former; then a series of three or four enlarged scale-shaped feathers turned backward from the gorget as far as the scapulars. With the exception of the vent feathers, which are whitish, the whole plumage is of

a very deep golden green, but brilliant in the lustre, and varying in different lights from greenish golden yellow to intense blue. The scaly feathers on the crest and gorget are the most brilliant. The tarsi and toes of this species are remarkably small, but very neatly formed. The female and the young are supposed to be without the rich gorget, and to have the under part more or less white; but they are very imperfectly known; and it is not improbable that some of them have been described as different species.

**BLUE AND GREEN HUMMING-BIRD** (*T. cyaneus*). This species is also a native of Brazil, and nearly of the same length as the former, only the tail is shorter, and though not so handsomely formed, it is a stouter bird. The bill is very nearly straight, of a bright yellow colour, a little enlarged at the base, and again near the tip, but with the points of the mandibles very sharp. The top of the head is dull green, but in particular lights it changes to the most intense ultramarine blue. The throat is of varying grey and blue, according as the light falls. The breast is nearly the same colours as the top of the head; the upper parts are golden green, with reflections of blue in some lights; and a streak from the eye to the shoulder on each side of the neck changes to golden yellow in some lights. The belly is brownish green; the tail feathers blackish blue; and the wings purplish grey. Nothing whatever is known of the plumage of the young or the female.

There are two or three other Brazilian species which resemble, in many respects, one or another of those last enumerated as inhabiting that country; but as they are known only as museum specimens, and are rare as such, we cannot be certain whether they are really species or merely some of the others in different states of plumage. There still remain one or two species, however, of this division which deserve notice, from the peculiar structure of the bill, which is curved upwards at the tip, nearly in the form of that of the avocets; but what particular purpose this singular form of bill serves in the economy of the birds has not been ascertained. So far as is known, they are found only in the Andes, and chiefly in Peru. They are both rare, and not much is known of their history. The two differ considerably in the markings of their colours, and the contour of the head, and also in the curvature of the bill; but in size, in general structure, and in the air and expression of the body, they are so much alike as to warrant us in concluding that there is a great similarity in their manners.

**AVOCET-BILLED HUMMING-BIRD** (*T. avocetta*). This is not a large species, but it is stouter both in the body and the legs than most of the humming-birds. It measures about three inches and a half in length, of which the bill takes up rather more than half an inch. The bill is very strong for the size of the bird, of a black colour, straight in the greater part, but turned upwards at the tip, where both mandibles are flattened, and very fine and sharp at the points; the gape extends far backwards, nearly to the eye, though under it in position, and indicates that the bird is in the habit of opening its bill widely for some purpose or other; the crown of the head, and all the upper parts generally, including the lesser coverts of the wings, are golden green, passing into greyish white along the sides of the neck, the shoulders, and the flanks; and backward to the under tail coverts; the chin, throat, and upper part of the breast are emerald

green; and the middle of the belly is black. The nest and the habits of the bird are entirely unknown.

**RECURVED-BILLED HUMMING-BIRD** (*T. recurvirostris*). This is a much more beautiful species than the former, and the shape of its bill differs still more from that of the majority of the family. It is longer by nearly one half, being about three quarters of an inch, while the entire length is only three inches and a quarter. Thus the body, exclusive of the tail, is little more than an inch long. The bill is strong and black, slightly curved downwards in the basal half of its length, but recurved upwards, beginning at about one third from the tip. From the beginning of the recurvature to within a short distance of the tip, the upper mandible is furnished on each side with small teeth reflected backwards, evidently showing that the bill is formed for seizing some solid substance, probably insects of some description or other, but of what kind or in what situation it is not easy to say. The whole anterior and upper part of the body is brilliant green, with rich metallic reflections, bluish in the tint on the upper part, and bright emerald on the throat and breast. The flanks are also pale golden green, ending in scallops at their under edge; and the middle of the belly is greyish white; the downy feathers upon the tibiae and the vent feathers are pure white; the tail is long and strong, but wedge-shaped; they are of various colours, being golden green in the middle, bluish at the sides, and showing bright copper or bronze reflections in some lights; the tarsi and toes are marked with alternate narrow rings of light and dark colour; the wings are very long, and falchion shaped, and of a blackish purple colour. We shall quote a short passage from Mr. Swainson, with reference to this and the preceding species. "The extraordinary formation," says Mr. S., "in the bill of this beautiful little creature is without parallel in any land bird yet described, and presents in miniature a striking resemblance to that of the avocet. It is almost impossible to conjecture rightly the use of this singular formation; but it appears to me not improbable that the principal sustenance of the bird may be drawn from the pendent bignoniaceæ and other similar plants, so common in South America, whose corollæ are long, and generally bent in their tube; the nectar, being at the bottom, could not be reached either by a straight or curved bill, though very easily by one corresponding to the shape of the flower.

"Bill black, depressed along the whole length, but more especially at the tip, which is rounded, thin, obtuse, and recurved in both mandibles, the under of which, towards the middle, has a convex swelling, which gives the recurvature a stronger appearance. All the upper plumage and body beneath golden green; from the breast to the vent is a stripe of black down the middle; thighs white; tail even; the two middle feathers dull greenish blue, the rest above obscure coppery brown, but beneath of a rich shining topaz colour."

**SUB-DIVISION II.—Cynanthus.** The birds of this subdivision also have the bill straight, or nearly so; but they differ from the former in having the tail very long and forked. They appear to range over a greater extent of latitude than those of the first subdivision.

**NORTHERN HUMMING-BIRD** (*C. colubris*). This species gets its common English name from being found in situations much more northerly than any of the others. It is the one which was first known in

this country, from its being so plentiful in North America; and for a considerable time it was the humming-bird. It is still the one with whose manners we are best acquainted. Its colours are, golden green above, golden red on the throat, very fine purple brown on the wings and tail, and white on the under part. It is a very beautiful species; and its whole length, from the tip of the bill to the extremity of the tail feathers, is not three inches and a half. In the southern parts of America it is stationary for the whole year; but it is a much more discurive bird than most of its congeners, and ranges seasonally over a considerable extent of latitude, breeding as far to the northward as Canada in the summer season, but retiring not only from the extreme north, but, generally speaking, from the whole country northward of the Gulf of Mexico during the winter. It makes its appearance in the southern states of America about the time of the vernal equinox, but it is at least a month later in arriving in the middle states, and it does not reach Canada till the summer has commenced. In the middle states it begins to construct its nest about a month after its arrival. The best description which we have of its manners is, of course, that given by Wilson, and therefore we shall not attempt to substitute another in place of it. "The nest is generally fixed on the upper side of a horizontal branch, not among the twigs but on the body of the branch itself. Yet I have known instances where it was attached by the side to an old moss-grown trunk; and others, where it was fastened on a strong rank stalk, or weed in the garden; but these cases were rare. In the woods it very often chooses a white oak sapling to build on; and in the orchard garden selects a pear-tree for that purpose; the branch is seldom more than ten feet from the ground. The nest is about an inch in diameter, and about as much deep; the outward coat is formed of small pieces of a small species of bluish grey lichen, that vegetates on old trees and fences, thickly glued over with the saliva of the bird, giving firmness and consistency to the whole, as well as keeping out moisture; within this are thick matted layers of the fine wings of certain flying seeds, closely laid together; and, lastly, the downy substance from the great mullein, and from the stalks of the common fern, lines the whole. The base of the nest is continued round the stem of the branch, to which it closely adheres; and when from below appears a mere mossy knot, or accidental protuberance. The eggs are two, pure white, and of equal thickness on both sides. On a person approaching their nest, the little proprietors dart around with a humming sound, passing frequently within a few inches of one's head; and, should the young be newly hatched, the female will resume her place on the nest even while you stand within a yard or two of the spot. The precise period of incubation I am unable to give; but the young are in the habit, a short time before they leave the nest, of thrusting their bills into the mouths of their parents, and sucking what they have brought them. I never could perceive that they carried them any animal food, though from circumstances, which will presently be mentioned, I think it highly probable that they do. As I have found their nests with eggs so late as the 12th of July, I do not doubt but that they frequently, and perhaps usually, raise two brood in the same season.

"The humming-bird is extremely fond of tubular flowers, and I have often stopped, with pleasure, to

observe his manœuvres among the blossoms of the trumpet-flower. When arrived before a thicket of these that are full blown, he poises or suspends himself on wing for the space of two or three seconds, so steadily, that his wings become invisible, or only like a mist; and you can plainly distinguish the pupil of his eye looking round with great quickness and circumspection; the glossy golden green of his back, and the fire of his throat, dazzling in the sun, form altogether a most interesting appearance. When he alights, which is frequently, he always prefers the small dead twigs of a tree, or bush, where he dresses and arranges his plumage with great dexterity. His only note is a single chirp, not louder than a small cricket or grasshopper, generally uttered while he passes from flower to flower, or when engaged in fights with his fellows; for, when two males meet at the same bush, or flower, a battle instantly takes place; and the combatants ascend in the air chirping, darting, and circling around each other, till the eye is no longer able to follow them. The conqueror, however, generally returns to reap the fruits of his victory. I have seen him attack, and for a few minutes tease, the king bird; and have also seen him, in his turn, assaulted by an humble-bee, which he soon put to flight. He is one of those few birds that are universally beloved; and amid the sweet dewy serenity of a summer's morning, his appearance among the arbours of honeysuckles, and beds of flowers, is truly interesting.

When morning dawns, and the blest sun again  
Lifts his red glories from the eastern main,  
Then through our woodbines, wet with glittering dew,  
The flower-fed humming-bird his round pursues;  
Sips, with inserted tube, the honey'd blooms,  
And chirps his gratitude as round he roams;  
While richest roses, though in crimson dress,  
Shrink from the splendour of his gorgeous breast.  
What heav'nly tints in mingling radiance fly!  
Each rapid movement gives a different dye;  
Like scales of burnish'd gold the dazzling show,  
Now sink to shade—now like a furnace glow!

"The singularity of this little bird has induced many persons to attempt to raise them from the nest, and accustom them to the cage. Mr. Capper, of Fairfax county, Virginia, a gentleman who has paid great attention to the manners and peculiarities of our native birds, told me that he raised and kept two for some months in a cage, supplying them with honey dissolved in water, on which they readily fed. As the sweetness of the liquor frequently brought small flies and gnats about the cage and cup, the birds amused themselves by snapping at them on the wing, and swallowing them with eagerness, so that these insects formed no inconsiderable part of their food. Mr. Charles Wilson Peale, proprietor of the museum, tells me, that he had two young humming-birds, which he raised from the nest. They used to fly about the room; and would frequently perch on Mrs. Peale's shoulder to be fed. When the sun shone strongly into the chamber he has observed them darting at the motes that floated in the light, as fly-catchers would after flies. In the summer of 1803, a nest of young humming-birds was brought me, that were nearly fit to fly. One of them actually flew out by the window the same evening, and, falling against a wall, was killed. The other refused food, and the next morning I could but just perceive that it had life. A lady in the house undertook to be its nurse, placed it in her bosom, and, as it began to revive, dissolved a little sugar in her mouth, into which she thrust its bill, and

it sucked with great avidity. In this manner it was brought up until fit for the cage. I kept it upwards of three months, supplied it with loaf sugar dissolved in water, which it preferred to honey and water, gave it fresh flowers every morning sprinkled with the liquid, and surrounded the space in which I kept it with gauze, that it might not injure itself. It appeared gay, active, and full of spirit, hovering from flower to flower as if in its native wilds, and always expressed, by its motions and chirping, great pleasure at seeing fresh flowers introduced into its cage. Numbers of people visited it from motives of curiosity, and I took every precaution to preserve it, if possible, through the winter. Unfortunately, however, by some means it got at large, and, flying about the room, so injured itself that it very soon died.

"This little bird is extremely susceptible of cold, and, if long deprived of the animating influence of the sun-beams, droops and soon dies. A very beautiful male was brought me this season (1806), which I put into a wire cage, and placed in a retired shaded part of the room; after fluttering about for some time, the weather being uncommonly cool, it clung by the wires, and hung in a seemingly terrified state for a whole forenoon. No motion whatever of the lungs could be perceived on the closest inspection, though at other times this is remarkably observable; the eyes were shut, and, when touched by the finger, it gave no signs of life or motion; I carried it out to the open air, and placed it directly in the rays of the sun, in a sheltered situation; in a few seconds respiration became very apparent, the bird breathed faster and faster, opened its eyes, and began to look about with as much vivacity as ever. After it had completely recovered, I restored it to liberty, and it flew off to the withered top of a pear-tree, where it sat for some time dressing its disordered plumage, and then shot off like a meteor.

"The flight of the humming-birds, from flower to flower, greatly resembles that of a bee, but is so much more rapid, that the latter appears a mere loiterer to him. He poises himself on wing, while he thrusts his long slender tubular tongue into the flowers in search of food. He sometimes enters a room by the window, examines the bouquets of flowers, and passes out of the opposite door or window. He has been known to take refuge in a hothouse during the cool nights of autumn, to go regularly out in the morning, and to return as regularly in the evening, for several days together."

The great extent of country over which this little creature passes, and the severe and almost incessant labour it undergoes, considering its very minute size, are not among the least wonderful facts in the whole history of animated nature. Upon examining a little more closely, we find some circumstances connected with it, which would convince us, if such a conviction were necessary, that the energy of animals, taken in their whole economy, is always in proportion to the development of its circulating system. The heart of this little bird is perhaps larger in proportion to the whole size than that of almost any other animal, in order that the rapidity of circulation, which is essential to the performance of the great and continued muscular efforts which the bird must make, may be supported by a corresponding nervous energy; the brain is also very large in proportion to the size of the bird; the stomach, on the other hand, is remarkably small, equal to a small fraction of the heart only, which

is very different from the relative size of the two organs in the majority of animals. In almost every specimen of this species which has been observed with sufficient attention, the stomach has been found to contain chiefly insects and their remains, which leaves no doubt as to the principal food of at least this species of humming-bird. One of the most extraordinary circumstances connected with it, is the varying colour of the plumage of the throat. We have mentioned golden red as the general tint, but according as the light falls on it, it varies through every hue, from deep black, in every imaginable shade of red and green, up to a glow of light, bearing some resemblance to the white heat of an intense furnace; and every one of those countless differences of colour has the same radiance of metallic mixture.

**BLUE-THROATED HUMMING-BIRD (*C. Lucifer*).** This is a very beautiful and delicately formed bird, with the bill very long, and slightly arched. The upper part is bright yellowish green, passing into greenish on the flanks, and into a tint nearly white on the under part of the body, which tint is purest on the sides of the neck, and contrasts well with the hind neck, where the green is deepest. The most striking character of the bird, however, is the ornamental feathers of the male; these consist of small ear-tufts of pale feathers directed backward, and not remarkable for their beauty; but the gorget under the throat, hanging down over the front and sides of the neck, is very splendid: it consists of well defined scale-shaped feathers, rounded at their extremities, and very neatly imbricated. The medium colour of these is a very pure bluish violet; but according to the refraction of the light, the colour varies from a fine pink to the most intense ultramarine blue. The wings are long and falciform shaped, of a brownish purple colour, and slightly bordered with whitish; the tail feathers are nearly of the same colour as the wings, with the exception of the middle ones, which are greenish yellow; the tail is much forked, and the lateral feathers are sharp pointed, with a little portion of the inner web, toward the tip, white. This species has been found in Mexico, but neither the female nor the nest has been described.

**AMETHYST HUMMING-BIRD (*C. amethystinus*).** This is a very beautiful species, and has been long known as a native both of Brazil and of Guiana. Its bill is long and straight, and its whole form neat; the upper parts are bright golden green, and the under grey, passing into greyish white on the lower part of the neck, and the under tail coverts. This last colour forms a sort of crescent round the lower margin of the gorget, which is composed of very compact scaly feathers, of a bright amethyst colour; the tail is deeply forked, and the lateral feathers slender and pointed. This is the marking of the adult male; but in the young birds there are considerable varieties of colour, and also in the form of the tail; in them, the feathers on the chin and throat have not the form of scales, and they are white; the tail also is not forked; the colour of the breast is gradually acquired; and so is the fork of the tail. In consequence of these changes, the bird is liable to be considered as several species; and there are, if not some varieties, at least some species, nearly resembling this one, of which specimens have occasionally been seen. The chief difference is in the colour of the gorget, which approaches to a ruby colour in some of them, while in others it has less of the reddish tint than occurs in the

common amethyst colour. There is, however, a good deal of confusion about these birds, arising from their agreement in some respects, and their difference in others; and a great deal of additional observation will be required before this confusion will be removed.

**WHITE-EARED HUMMING-BIRD** (*C. leucotis*). This is a Brazilian species, of small size, but handsome and peculiar in its markings; the length is not more than three inches; the bill is not very long, of a yellow colour, and slightly arched; the forehead, before the eye, the chin, cheeks, and upper sides of the neck, are azure blue, less conspicuous in the tint on the forehead where the feathers are small, but becoming more brilliant downwards, as the feathers get larger in size; the colour on the side of the head to the rear of the eye, is broken by an arch of white which passes over the ear covert, and curves downward, the one nearly meeting the other on the back of the neck. It is from the last marking that it receives the name of white-eared. The gorget on the lower neck and breast is bright verdigris, or slightly bluish green; the hind head is brownish violet, which gradually blends with the golden green on the back; the under part is brownish green, with a trace of grey; the quills of the wings purplish; the tail feathers, which are nearly even at the extremity, of the same colour as the upper part of the bird; and the vent feathers and under tail coverts pure white. It is by no means common in Brazil, and specimens of it are rare in European collections.

**EVENING HUMMING-BIRD** (*C. vesper*). This species has been observed chiefly in the southern Andes, or at least in those elevated plains which lie between those mountains and the sea. Some of the colours of this species are more subdued than they are in most of the others; but they are beautifully contrasted. The bill is long, slightly curved and enlarged near the point. The upper part is oil green, passing into more of a golden green on the middle of the back and the rump, but without metallic reflections. The breast and belly are white, and so are the under coverts of the tail; but the flanks and the vent feathers are greyish. There is a small streak of white behind the eye, and another behind the gape; the wings and tail are deep purplish black, both very long, and the tail much forked. The most beautiful part of the bird, the gorget, which covers the chin and fore neck, consists of scale-shaped feathers, and is of that peculiar reddish violet, which changes into bright ruby in the one extreme of reflection, and into rich sapphire blue in the other.

**RACKET-TAILED HUMMING-BIRD** (*C. platyrus*). — There are two distinct species of these birds, both of which have that peculiar structure of the exterior feathers of the tail upon which the trivial name is founded,—namely, the feathers very elongated, and the webs gradually tapering away till they are almost obliterated, and then spreading again into an oval disc, which is very distant, not only from the body of the bird, but also from the other feathers of the tail, which, for nearly as long as the body exclusively of the bill, are not half the length of the racket feathers.

These two species are, the racket-tailed humming-bird, with the tarsi the same as in the rest of the family; and the rough-legged one, with the tarsi feathered down to the toes, or at least clothed with a downy covering in very considerable quantity.

The racket-tailed humming-bird is deep and

rather dull green on the upper part, of uniform tint throughout; it is dull brown, with a greenish tinge, on the under part; the vent and under coverts of the tail are pure white; and the chin and throat and upper part of the breast are covered with a gorget of very bright emerald green. The two outside feathers of the tail extend to twice the length of the others, tapering gradually for the greater part of their length, and then terminating in firm broad discs of a black colour, which are nearly round. The wings are long, narrow, and falchion-shaped. Enough is not known of the habits of this singularly formed bird for enabling us to ascertain whether the female also possesses those rack feathers, or whether they are peculiar to the male. Analogy, however, would lead us to conclude that the latter is the case; because there are comparatively few birds in which the female has any supplemental feathers in the tail. The remaining tail feathers are gradually shorter towards the middle, and form a slight fork; but when the racket feathers are taken into account, the tail is very much forked. These birds are rare, and little is known respecting them, farther than that they have been brought to Europe from Guiana.

The rough-legged humming-bird is more handsome in the colouring than the smooth-legged racket-tail. All the upper parts are very rich golden green, with the exception of a white bar on the rump; and the two middle feathers of the tail are of the same colour. The gorget, which is very bright emerald green, descends far down on the breast, as does also the green of the back on the sides and flanks, which passes into deep brownish green on the middle of the belly. There are feathers on the tarsi, and also on the tibiae, and though those feathers are formed of very small filaments, those filaments are not downy, like the feathering on the tarsi of the birds of cold countries. They partake of that firmness of texture which characterises the general plumage of the humming-birds. This covering of the feet is a peculiarity among birds; and therefore it is to be regretted that we do not know either the habits, or the native country of this species, farther than that it is American; and, therefore, we can form no conclusion respecting the purpose which this formation, of which it is the solitary instance in a very numerous family, answers in the economy of the bird. Besides the difference in the colour and the more remarkable difference in the tarsi, of which we have taken notice, there is a considerable difference in the shape of the rackets in which the tails of these birds terminate; in the one with a naked tarsi, these are nearly round; but in the other they are oval, or rather sub-oval, with pointed extremities.

**HALF-TAILED HUMMING-BIRD** (*C. erricurus*). This is a very gracefully formed, though remarkably slender bird. It measures about four inches and a quarter in length, of which more than one half is occupied by the tail, and at least a third of the remainder by the bill. The bill is slender, a little enlarged near the tip, but remarkably sharp pointed. It is very slightly bent. The body is elongated, and gracefully tapered off towards the tail. The tarsi and toes are very slender. The upper parts of the body, including the coverts of the wings, and the two middle feathers of the tail, as well as the last coverts of the tail, which, though short, consist of two feathers similar in structure to the others, are golden green; and all the under part from the middle of the breast, including the

under coverts of the tail, is of the same colour. The gorget is rich purple, or ultramarine blue in some lights, and formed of scaly feathers; below it there is an irregular band of white, extending backwards on each side of the neck till the two ends nearly meet; and below this there is a pretty large patch of bright yellow, broadest on the breast, but extending on the sides of the lower neck and the shoulders as far back as the patch of white. The wings and tail are purple brown; the former long in proportion to the size and weight of the body, but short as compared with the tail. The tail itself is the most remarkable part of the whole structure; and is not very well expressed by the English epithet, half-tailed. The French name "singular" is more expressive of it; because all the appendage that nature bestows upon any particular species of bird is, of course, a whole tail, whether it consists of a number of feathers or of one only. This one consists only of six, unless we are to admit the last coverts to be reckoned as tail feathers; and even the two longest of those green ones are so short in comparison that they appear like coverts to the produced ones; and they do this the more by being of the same colour with the back; while the produced ones, being of the same purple brown as the wings, contrast strongly with them. The external tail feathers are the longest, and they diverge at the points; while the other two reach to about two-thirds of their length. All these four feathers are narrow, and of equal length throughout, only they are rounded off at the points. By a very little contrivance, a figure of this bird may be readily converted into a most ludicrous caricature of a human being. All that has to be done is to turn the figure with the tail feathers directly downwards, lay a little slip of paper over the head and neck of the bird as far as the shoulders, continue the same tint of green upon the paper in the form of the collar of a coat, paint the back of a human head above this collar, and the caricature is complete,—representing a most singular being with a green coat and epaulettes, and purple brown sleeves, with trowsers of the same upon long stilt-like legs; for the skirts and pocket-flaps of the coat are very well made out by the two green tail feathers and their coverts.

**BAR-TAILED HUMMING-BIRD** (*C. sparganurus*). This is a most singular species, and considerably larger than many of the others. It is understood to inhabit a considerable extent of the table-land of the Andes, both in Mexico and Peru; but it has not hitherto been found in any of the coast countries or the islands. The bill is a little bent, awl-shaped, and very sharp at the point. The upper parts are golden green, with a slight tinge of purplish brown; the under part from the bill to the middle of the belly is bright emerald green, peculiarly rich on the middle of the throat, and composed of scaly feathers which extend along the whole of the breast. The lower part of the belly is all green, and the vent feathers greyish white. The rump is clear and rich red, but without any metallic lustre, and the feathers have not a scaly appearance. The tail, however, is the most singular part of this bird. It consists of two parts, standing at an angle to each other like the letter V. The outside feather in each branch is very long, not less than six inches. The second feather is only about three inches and a half, the third a little more than two inches, the fourth shorter than that, and the last one about three quarters of an inch. The principal colour of these

feathers is bright reddish orange, of a very brilliant metallic lustre, and varying in different lights through different shades from red to yellow. There is a black bar across the end of each feather, which shortens as the feathers shorten. This bar is carried down the outer margin of every feather except the first and second, and the basal two thirds of the first has also the outer margin black. Where the margin is black, the shaft of the feather is also black, and where there is no black margin, the shaft is relieved by a slender black line upon each side. Altogether, it is one of the most singular appendages to be met with in the whole feathered creation; and though we are not very well informed with regard to the manners of many of the family, the strong fortification of coverts which this tail possesses would lead us to conclude that it is capable of some corresponding action which is essential to the economy of the bird.

**NUNA HUMMING-BIRD** (*C. Nuna*). This species has some resemblance to the preceding one in its general form, and the development of the several parts, especially the tail, but it is of much smaller size, the bill and body only measuring two inches, and the tail three. In its colouring it is very beautiful. The whole of the upper part is a fine emerald green, with rich golden reflections, and the general ground colour of the under part is pure white. But this under part is very beautifully marked with circular spots of emerald green, one upon the tip of each feather, and these show very richly upon the pure white ground. These are most perfect, and become gradually faint and clouded towards the lower part of the belly, till the colour passes gradually into bright chestnut on the under coverts of the tail. The tail feathers are of considerable breadth for the size of the bird, and they increase in length from the middle to the outer ones, in the same manner as in the bar-tailed species. The colours are, however, more varied. The middle ones are purple brown on the basal part, steel blue beyond that, and terminated by a bar of very beautiful green. The lateral feathers have the tips deep steel blue, and the outer web white for the basal half of their length. The young have the colour broken by grey on the upper part, and brownish red on the under. Hitherto, we believe, specimens of this very handsome species have been obtained only from Peru; but it is probable that they occur also in Brazil.

**LANGSDORFF'S HUMMING-BIRD** (*C. Langsdorffii*). Is a Brazilian species, and as remarkable for its beauty as for the singular form of the tail feathers. The bill is of moderate length, very slender and depressed at the base. The upper part is a delicate subdued golden green; the gorget consists of scale-formed feathers of the same general tint, but giving out brilliant reflections in different lights. On the under part, this is bordered by a crescent of bright orange, which has reflections of golden yellow and of red. The lower part of the breast is intense blue; the belly brownish violet; and the vent feathers, under the tail coverts, pure white, which ascends on the hinder part of the flank, and, uniting on the lower part of the back, separates the green on the rump from that on the rest of the body. The wings are purplish grey with a dash of orange on the turn. The tail feathers are ten in number, six in the middle, which are deep blue, broad at the bases and narrow at the points, the two middle ones comparatively short, and the others longer and more pointed in suc-

cession. The most singular part of the tail, however, is the four remaining feathers. These are of the same colour as the wings, and taper gradually to perfect points, the inner pair being nearly twice the length of the blue feathers, and the outer pair a good deal more. This peculiar production of the tail feathers is characteristic of the mature birds only, as is also the brilliant green and the orange crescent on the throat and breast. The outline of this species is particularly graceful.

**BLACK-CAPPED HUMMING-BIRD** (*C. polytmus*). This is another very elegant species, remarkable for the length to which the feathers of the tail are produced. It has been procured for this country chiefly from the island of Jamaica, where it is far from being rare; but it occurs also in many others of the West India islands, and also on the main land of South America. Estimated by the length, it is a bird of considerable size, for it measures nine inches from the extremity of the bill to that of the produced feathers of the tail. Of these nine inches, however, the tail occupies two-thirds, and the bill one-third of the remainder, so that the length of the body and head is reduced to two inches. The wings are long and powerful as compared with the size and weight of the body, but short as compared with the tail; and thus the bird, when it hovers about, has some resemblance to a dragon-fly on the wing. The bill is very slightly curved, lemon yellow for the greater part of its length, and black at the tip. The tarsi and toes are reddish yellow. The whole upper part of the head is covered with black feathers considerably produced, of a silky texture, and without any metallic reflections. The rest of the body, with the exception of the gorget and the under tail coverts, is rich golden green; the gorget is scaly, and emerald green of the utmost intensity of tint; and the under tail coverts are grey, with greyish purple tips. The wings are deep brownish black, with a tinge of purple. The tail is much forked, and consists of ten feathers; the middle ones are short, and three others on each side increase in length by nearly equal stages, while the two external ones reach beyond the longest of the others for a length nearly equal to that of the bill, body and other tail feathers taken together. They are rather narrow, but of uniform breadth throughout, and the produced part of them is flexible and waving. The general colour of the tail is brownish black with reflections varying from purplish grey to bright green. The female has the under part white, breaking with the green on the sides of the neck. The tail wants the produced feathers, and is green, with the exception of about half the length of each of the four external ones towards the tip, which is white.

**DUPONT'S HUMMING-BIRD** (*C. Dupontii*). This is a slender species, with the bill very long, and the tail of considerable length, though not so much so as in the previously noticed species. The entire length is about four inches, of which the bill and tail occupy nearly one half. The bill is long and slender, with very little curvature, and exceedingly sharp at the point; the upper part is yellowish green, of a glittering lustre, but not metallic; the gorget, which rises so high as nearly to include the eyes, and extends far back on the sides of the neck, consists of scaly feathers, and varies from intense black to rich deep blue, according to the light in which it is seen; the flanks and belly are pale brownish green, passing into whitish on the shoulders, and pure white on the vent; the tail con-

sists of ten feathers, extending by gradually increasing differences from the central ones, which are very short, to the external ones, which are rather long, and have their extremities slightly rocket shaped; they have white tips succeeded by fawn colour, and then by a reddish tinge at the base; the wings, with the exception of the lesser coverts, which are like the upper part, are purple brown, of mean length, very narrow, and falcion shaped. The bird is a native of Mexico, and probably also of some of the other elevated plains among the Andes.

**SAPPHIRE-THROATED HUMMING-BIRD** (*C. sapphirinus*). This is rather a showy species, about three inches and a half in length, of which the wings and tail occupy about a half; the body is stout for the size of the bird, and the wings are rather long; the bill is long, slender, very little bent, bright yellow for the greater part of its length, but black at the tip; the top of the head and all the upper parts of the body are rich golden green, which passes into brownish green on the flanks and belly, and into grey on the vent feathers; the chin is clear reddish chestnut, and below that there is an extensive gorget of beautiful sapphire blue extending down to the middle of the breast, and composed of scaly feathers; the extremity of the tail is nearly even, and the colour a uniform madder red. The female wants the red on the chin, and is every way duller in the colours. This species is pretty generally distributed, being found along the whole northern-coast of South America from Brazil westwards; and it is not rare in its localities.

**WAGLER'S HUMMING-BIRD** (*C. Wagleri*). In its form this bird bears some resemblance to the species last mentioned, but its colouring is very different. The whole plumage, including even the wings and tail feathers, is nearly of one uniform tint, namely, deep and rather dull emerald green, almost black in the shade, and inclining to a dull bluish tint on the quills and tail feathers. The body, however, possesses very rich reflections of blue and gold, according as it is turned to the light, and the quills and tail feathers furnish equally rich reflections of purple. The bill is long, perfectly straight, and slender; and the wings, though rather narrow, are long and falcion-shaped. The tail is strong and broad, composed of ten feathers, and forked at the extremity. This species is a native of Brazil.

**SAPPHIRE AND EMERALD HUMMING-BIRD** (*C. bicolor*). In form this species resembles the last-mentioned, but its colours are different. The green on the upper part is richer; and the colour of the throat, the breast, and the tail, is much bluer. The former indeed forms a gorget of very rich blue of bright metallic lustre, which fades gradually into bluish green on the belly. The tail is steel blue on both surfaces, and very little forked. The female has the throat and breast nearly white, and the rest of the under part only mottled with green. The young males have the blue gorget very dull, the flanks and vent feathers of a greenish black colour; and the whole plumage without that brilliancy which characterises the full-grown male. It is found in the low and rich countries in the north part of South America, and also in several of the West India islands; but it does not occur, or at all events has not been met with, in elevated countries, such as Mexico and Upper Peru.

**FORKED-TAILED VIOLET HUMMING-BIRD** (*C. furcatus*). This species is not so forked in the tail as some of the others; but as it happened to be the first forked-

tailed one which was known to Europeans, it has got possession of the name. It is four inches in length; and as the tail is not so long in proportion as some of the others, the body is longer, and it is also thicker. The upper parts are golden blue in the middle, passing into golden green on the wings and the tail, and into the same colour with a trace of brown on the head; the vent feathers are grey; the gorget on the throat is of a beautiful amethyst purple; the middle of the under part is pure white; and though the upper part generally appears blue in some lights, it appears golden green in others. It occurs pretty generally in the northern parts of South America, from Brazil westward, and also in the West India islands; but though it has been long known, its habits have not been ascertained, neither have the colours of the female or the young been accurately determined.

**BLUE-BELLIED HUMMING-BIRD WITH TOOTHED BILL** (*C. thalassinus*). This is a Mexican species, about five inches in length, with the tail very fully developed, and the wings very long, narrow, and bent. There is not a great deal of variety or strong contrast in the colours; but they are rich and beautiful. The general colour of the upper part of the body is very dark green, with golden reflections of rich metallic lustre. The gorget upon the centre of the throat varies from deep velvet black to bright emerald green, with metallic reflections; and this gradually passes into a fine azure blue on the ear-tufts. The tail is greyish blue with metallic lustre, and crossed by a bar of deep indigo blue near the extremity. The bill is slightly bent, and both mandibles are toothed for a short distance near the tip. The bill is of a black colour, as are also the feet. The young males are without the rich blue on the ear-tufts and the sides of the neck; and in them the whole of the upper part is mixed with greyish blue, much more than in those which are full grown. The female is understood to have the flanks and vent feathers dull grey, and the under tail coverts reddish white, and also to be without any of the rich blue on the sides of the neck or the lower part of the breast. This is rather a rare species.

**GIGANTIC HUMMING-BIRD** (*C. gigas*). This is the largest humming-bird which has hitherto been discovered. It is at least eight inches in length, and stoutly made, remarkable for the length and strength of its wings, and the firmness and regularity of its tail, which last organ is rather deeply but regularly forked at the tip. From its large size, it has been called "the Patagonian;" and it is rather curious that if it is not found actually within Patagonia, it is found close upon the borders of it. The first knowledge that was obtained of it in Europe was from a specimen brought by the gallant but unfortunate Lord Byron from the country of the Aracanians, the whole of which lies beyond the thirty-seventh degree of south latitude. It is also common in the interior of Chili, but it is understood to be rare nearer the equator, and not found in the northern parts of South America, though it was once considered as being a Brazilian bird. Its colours are not nearly so bright as many of the smaller species; and it is described as being without any brilliant gorget or produced feathers. It is an inhabitant of the wild woods, in which it is not frequently seen; and therefore its manners, or the changes of plumage it may undergo, are very imperfectly known. The top of the head, the back, and the coverts of the wings,

are brownish green, with green reflections; the under parts are of a dull pale reddish, mottled with a darker tint, and passing into dull green on the flanks. The head and upper part of the throat have a mottled appearance; and though there is no beauty of colour in the fore-neck, the feathers have the scaly form which belongs to the males of almost all the family; and as their margins are of a paler tint than the central parts, this part also appears slightly mottled. The tail consists of ten feathers, of a greenish brown colour, with reflections of golden green, but not very brilliant. Altogether, indeed, this bird is more sober in its plumage than almost any other of the family. It is, however, a very perfect model of a flying bird. The closed wings extend beyond the extremities of the tail, and their form and their feathers are alike fitted for the most vigorous flight. The pectoral muscles are also very large, in order to give motion to the powerful wings upon which the strength of the bird is concentrated. The feet, on the other hand, are remarkably small, and appear quite disproportioned to the size of the bird. In the male the quills of the wings are said to be violet brown, without any mixture of other colours; and in the female they are said to have pale russet colour on the margins; but there is a good deal of confusion about the descriptions of these birds.

There are a good many more species described as belonging to this sub-division; but some of them are doubtful, and all of them but little known, and therefore the list which we have given may perhaps be considered as sufficient for the general reader. It is only now that America, more especially the tropical and southern parts of it, is beginning to be examined with anything like zeal and science united; and as the harvest of discovery in the natural history of birds, and in every other department of nature, cannot fail in being very rich, we may confidently expect that, in the course of a few years, we shall be as well acquainted with the habits of American animals, and humming-birds among the rest, as we are now ignorant of them.

**SUB-DIVISION III.—Phæthornis.** The general characters of this sub-division are the bill long, tapering to the point, and considerably arched; and the tail long and wedge shaped, or stayed by each feather being a little longer than the one exterior of it, as in the magpie.

**SUPERCILIOUS HUMMING-BIRD** (*P. superciliosus*). The bill of this species is very long, and tapers gradually to the tip, being also considerably bent. The male and female differ considerably from each other in size, in the general colours of the plumage, and in the general form of the tail feathers; the upper part is bronzed green, with a brownish tint; the side of the head is marked by two patches of reddish white, one passing from the base of the upper mandible to the ear covert, and the other consisting of a spot immediately over the eye, and it is from the latter that the bird gets the name of supercilious, or eye-browed; the throat and upper part of the breast are covered with scaly feathers, but these have no brilliant tint, the whole of the under part being a subdued brownish white, very soft and delicate, but without much beauty; the tail is wedge shaped, but contains two produced feathers which extend an inch and a half beyond the others, and are very straight and narrow; the tail is bronzed green, deepening toward the extremities of the feathers, which are lancet shaped, and

have narrow borders of a paler colour; the length of the bill, measured along the curve, is more than an inch and a-half; that of the body to the insertion of the tail is three inches, which last is also the entire length of the tail. The bird is thus rather more than seven inches and a half in length, but as three-fifths of this are taken up by the bill and the tail, the body is not large. The female, taken altogether, is much richer in the plumage than the male, which is very unusual in this family of birds; the upper part is bronze green, as well as in the other, but the tint is clearer, and it is pleasingly variegated by narrow borders of brighter green on the points of the feathers; the white streak under the eye is also brighter, but the spot above it is less conspicuous; the under parts are of a deeper and finer brown, darkest on the chin, and becoming paler backwards; the tail is rounded at the extremity, and very finely coloured; the middle feathers are longer than the rest, but not produced, so as to break the general outline: they are bright green, with the exception of the tips, which are white, and immediately within the white tips there is a broad bar of the same green as the rest, but deeper; the lateral feathers of the tail are reddish chestnut in the basal part, white at the tips, and have a black bar inside the white, which, alone with the green on the middle feathers, forms a zig-zag band across the whole tail; the length of the female is less than five inches, of which the body occupies one-half, and the bill and tail the other half, in equal parts. These birds are found in most of the rich parts in the tropical portion of South America.

**SCALY-BACKED HUMMING-BIRD** (*P. Eurynomus*). This is an elegant species, and alike remarkable for the peculiarities of its markings, and the form of its tail; it has some resemblance to the last-mentioned species, but it is rather shorter, more slender in the body, and altogether much more elegant; its total length, including that of the produced feathers of the tail, is about six inches and a half, and the bill and tail occupy considerably more than half; the outline is altogether exceedingly elegant; the bill has a slight, but very graceful curvature; the tail is particularly handsome in shape; and the wings, which are very long and powerful for the size of the bird, form graceful curves; the head and nape of the neck are covered with scaly feathers of a brown colour, margined with chestnut; the other upper parts are of a fresh green; the plumes have the shape of scales, they are large, rounded, and bordered with a dull reddish tinge; the principal streak on the ear coverts is black, above which, from the eye backwards, there extends a stripe of ochre yellow, separating this black from the brown and chestnut feathers on the head and nape, and a similar line extending from the gape below the eye and the ear coverts; the chin and throat are covered with scaly feathers, brown in the centre, and margined with ochreous yellow; the neck, breast, belly, and flanks, are brownish grey, with a reddish tinge; the lower tail coverts are reddish chestnut; the tail is of a wedge shape; the centre feathers are green, very long and narrow, with the projecting tips white; at the base, the other feathers are of a deep black, with white tips, which extend to nearly half their length. It is a Brazilian species.

**GUY'S HUMMING-BIRD** (*P. Guyi*). This species is the nearest approach we have to the supercilious humming-bird, and indeed it has often been mistaken for it. Nor is this to be wondered at, for it is exactly

of the same form, though of rather smaller dimensions. It differs, however, in some other respects also. The projecting feathers over-stretch the tail for a much less distance. These feathers above are golden green at the base, farther outward they are black, the tips of the lateral feathers are fringed with white, and the projecting narrow parts of the centre plumes are also white. The bill is rather long, the under mandible orange-red verging to brownish at the tip; the feathers on the upper parts of the body are of a brilliant metallic green, and those on the crown have a reddish border. The ground of the auriculars is black, margined above and underneath by a dull yellow line; the chin, in form, is like a small gorget, and is of a bright chestnut; the remaining under parts are deep bluish grey, which, on the centre of the belly and on the vent, in different lights, changes to a reddish yellow; the lower tail coverts are altogether white. We have no account that can be relied on respecting the native country of this bird.

**INTERMEDIATE HUMMING-BIRD** (*P. intermedius*). This species is a native of Brazil; its length is about three inches and a half, and the general colour of its plumage is reddish brown, but on the rump, belly, and vent, it approaches to a senna colour; the auriculars are black, and under these and above the eye there is a pale yellow stripe; the centre feathers of the tail do not exceed the others in length more than half an inch; they taper gradually from the base, the projecting part is pure white, the other parts are black, and the outer one is fringed with reddish brown; the under mandible of the bill, at its base, is pink, farther out it is black, then pink again, and terminates with a black tip.

**BOURCIER'S HUMMING-BIRD** (*P. Bourcierii*). This is a Brazilian species, and is supposed to inhabit the mountainous districts. The prevailing tint over the upper parts is reddish green, and it resembles the scaly-backed species in so far as each feather on these parts is bordered with reddish brown; its tail is of ample dimensions, and the centre feathers are proportionally so; the upper side is greenish black, deepening in tint towards the tip, where a chestnut spot marks the outer web; the long feathers are tipped with white, where they exceed the length of the tail, and underneath a brown tinge characterises the whole; the crown is reddish green, the throat white, and the other under parts reddish grey, most bright on the sides of the neck. In various lights traces of the supercilious streak and that from the rictus are visible in this species.

**BROWN BRAZILIAN HUMMING-BIRD** (*P. squalidus*). This is also a Brazilian species. From its colouring and general appearance, so closely resembling the supercilious humming-bird, it has been supposed by some to be a climatal variety of that species; but it does not appear that there is any rational ground for such a conclusion, seeing that it is scarcely one half the size of the supercilious, and that it differs materially from it in other respects. The feathers of the upper parts of the brown Brazilian humming-bird are of a dull brownish green; those of the throat of a dull grey, with dark centres; and the covering of the breast is of the same colour, while that of the belly and vent is of a tawny yellow. The tail-feathers are brown, tipped with white, and the centre ones of the same organ, so far as they extend over it, are entirely white. Over the eye is a strongly marked reddish yellow stripe, the auriculars beneath are deep brown,

and the undermost of these is joined with the rictus by another stripe which entirely encircles the eye and ear coverts.

LONGUEMARE'S HUMMING-BIRD (*P. Longuemareus*). This species is a native of Cayenne. It is about three inches eight lines in length. The prevailing colour of the upper parts is brownish red, with brilliant metallic reflections of a green lustre on the back; the feathers on the top of the head, which form a sort of cowl, are dark reddish brown, and the sides of the neck are of the same colour; the under parts are reddish yellow, a shade darker on the throat and breast; the under coverts of the tail are pure white; the tail is wedge shaped, of considerable length, but the centre feathers do not extend nearly so much beyond the others as in some of the species we have just noticed.

RED-BELLIED HUMMING-BIRD (*P. rufigaster*). This pretty little bird is only three inches in length from the tip of the bill to the end of the tail. The bill and tail occupy about two-thirds of the extreme length, so that the body is not more than one inch long; the crown is of a greyish colour, and above a supercilious stripe of white extends to the ear coverts; the upper parts of the back and neck are of a chestnut red, with golden green reflections; the under parts are also of this colour, except that it is of a lighter shade on the throat, and changes to a yellowish white tinge on the chin; the tail is brown, tinged with reddish white; the centre feathers are beautified with golden green reflections, and the extending tips are pure white. It is a native of Brazil.

DAVID'S HUMMING-BIRD (*P. Davidianus*). A figure of this species is given in No. 2 of the plate HUMMING BIRDS. It is nearly of the same size and form as the red-bellied species. The general tint of the plumage is brown, paler, and slightly mottled with yellowish on the under part. The top of the head is furnished with produced feathers, which form a crest of considerable length; the tail is broad and rounded. It is found on the continental part of tropical America, and named by Lessou after David the French painter.

HAIRY-LEGGED HUMMING-BIRD (*P. hirsutus*). The tarsi of this species are not so completely feathered as those of the hairy-legged rocket-tail formerly described; but still they are sufficiently so for entitling the bird to the name by which it is known. It is by no means a rare species, being found in many of the West India islands, and also in Mexico, though it is said not to be very common in the latter country. It is about four inches in length, of which the bill and tail occupy about the half. The bill is regularly but not greatly curved, rather stout at the base, and tapering gradually to the tip; the upper parts are of a shining brownish green with bronze-coloured reflections, except some of the lesser coverts of the wings, which are bluish; the under parts are bright reddish brown; the tail is of a similar colour, but redder; the tips of all the feathers, save the centre ones, are white; and immediately within the white there is a broad black bar.

SWAINSON'S HUMMING-BIRD (*P. Swainsonii*). This species was first described as a Brazilian bird by Swainson; it is about three inches in length, and has the upper part yellowish green, with yellow margins to some of the feathers, and the under part chestnut; the middle feathers of the tail are green, the others yellow with white tips, and within the white there is a bar of black crossing the feathers.

There are several species, or varieties, resembling these in many of their characters, to be met with in museums and collections, almost all of which have been brought from central America, but their history is so well known, that a mere enumeration of their colonies would be waste of time.

SAW-BILLED SPOTTED HUMMING-BIRD (*P. navosus*). This bird has been found chiefly, if not exclusively, in the mountainous parts of Brazil, near Rios, to which we have already alluded as being the favourite resort of a vast number of this curious species of birds. Its length is about five inches; the whole of the upper parts are olive green, with metallic reflections, which are very brilliant, especially on the shoulders and wing-coverts; the ear-coverts, as well as a tuft of produced feathers which passes down the sides of the neck, are of a bright reddish brown, deeper under the eye, and at the extremities of the auriculars, where it contrasts beautifully in relief with a pale stripe of a similar colour, that extends from the eye; the wings are of great strength, and the shafts are of proportional power; their colour is purplish green; the tail is rounded; the middle feathers, as well as the basal parts of the outer ones, are of a similar colour to the wings; the outer feathers, next the centre, are of a pale yellowish brown at the tips, and in the other feathers, taken outward from the centre, this yellowish portion becomes gradually more extended, which gives a bold relief to the dark spots on the rest of the feathers. The bill of this bird is the most singular part of its structure; it is long, strong, rather broad, straight in the greater part of the length, but curving slightly downwards in the upper mandible, and very slightly upwards in the under one, which is shorter than the other; the portion of the upper one which extends beyond the under, forms a little hook, and both mandibles are, for about one-third of their length from the hook, armed with pretty strong teeth directed backwards, and thus resembling the mandibles of the mergansers, and some other aquatic birds, which seize their prey by a rapid snatch with the bill while they are driving through the water. From this structure of the bill, it is natural to conclude that those birds seize their food on the wing, not by straight-forward flight like the swifts, as the form of the tail does not adapt them for beating the air in the same manner as the swifts do; but as the breadth and power of the tail enable them to ascend and descend with great rapidity, it is probable that they snatch small insects from the flowers and leaves of plants, or even from the ground, without alighting, and their very small and weak feet are proof that they are not in any way ground birds, or capable of using the foot for any other purpose than simply that of perching. It is worthy of remark, too, that in this species, as well as in the others that are decidedly mountainous, we find a breaking or mottling of the colours, which is not found in the species which inhabit the low and warm places. Thus we have, as it were, even in birds which may be said to be chiefly tropical, as well as wholly American, some sort of approximation to the variety of colour which characterises the birds of different climates. On the eastern continent the tropical birds, generally speaking, have their colours entire, and are remarkable either for the beauty of their tints, or the brilliancy of their metallic lustres. The birds of the colder climates again have their colours more broken, more sober in the tints, less brilliant in metallic reflections, and very seldom that that scaly

form which is so characteristic of many of the humming-birds; their feathers, in short, have more the structure of clothing feathers which protect them from the general temperature of the weather, while the tropical plumage which breaks the sun-beams into so many colours by refraction appears to be more a protection against the action of that luminary. From this circumstance, a humming-bird, in all probability, while it scatters the solar light around it in all those radiant lustres that are so much admired, remains unaffected, and able to perform its very arduous and incessant labour, under a degree of fervour which would send the ordinary birds of our country panting to the earth, or compel them to seek the cover of the thick foliage, as most of our birds do in the sultry hours of the summer's day. The humming-birds appear to be possessed of this faculty in a much higher degree than the larger birds which are natives of the same climate, and inhabit the same places; for, as is the case with our birds, these last are driven to the shade during the heat of the day, and the fervid sun-beam is left to the humming-birds, as the genuine children of the sun.

SUB-DIVISION IV. — (*Campylopterus*). Literally "curved wing," but the usual name given to this form of wings is *sabre-wing*, or *sickle-wing*, the wing being so much bent as to have some slight resemblance to one or another of these implements. The characters of this sub-division stated in brief are: the wings much bent, with the basal parts of the shafts very much enlarged and compressed; and the tail is rounded, or staged, by having the longest feathers in the middle, and those towards the sides gradually shorter. The bill is rather long, a little bent, and there is sometimes a slight approximation to a tooth, in an angular elevation near the tip of the upper mandible. These wings, from the peculiar form of the shafts of the quills, are stiffer and stronger in proportion to their size than the wings of almost any other birds whatever. The greater number of them frequent damp woods and the margins of streams; and in all probability subsist chiefly upon insect food; and from the nature of the places which they haunt, specimens are rare, and the birds themselves are rarely seen.

BLUE-THROATED SABRE-WING (*C. latipennis*).—The trivial name *latipennis* is not given to this bird on account of the breadth of the webs of the feathers, but on account of that of the shafts; though the wings themselves are very long, and the quills very much bent. Hitherto the specimens have been procured from some of the West-India islands, especially from the island of Tobago; but as that island lies at no great distance from the lower valley of the Orinoco, it is probable that the same birds are also found in that valley. The length is nearly five inches and a half; the bill of moderate length considered as the bill of a humming-bird; the wings long and powerful; and the tail also powerful and of considerable extent, though not much longer than the closed wings. The general colour of the body is golden green, very rich and beautiful on the upper parts, and extending over the lesser coverts of the wings, and the middle feathers of the tail; but in the under part it has more of a yellowish tinge. The common English name is given from the gorget, which is of a beautiful violet blue in the middle part, passing into blackish blue on the sides, but brilliant through its whole extent. It is composed of scale-shaped feathers, and extends from

the gape to the ear-coverts in nearly a straight line upon each side; but the upper part of the ear-covert consists of two or three small green feathers immediately behind and under the eye. It is rounded in the under part, and extends only over the chin and throat. The wings are purplish black; and the centre feathers of the tail, though in some lights of nearly the same green as the back, are almost black in other lights. The next pair are raven black, or black with bluish reflections; and the three exterior ones on each side have white tips for a considerable part of their length. They are not so much day birds as some others of the genus, but make their appearance in greatest numbers in the evenings; and some reports state that they shift their ground with the seasons.

Other species, differing little from this one, excepting in colours, are found in various parts of the West Indies and South America; but they occur only in low-lying places; and though there is a Mexican species, occurring on the table-land of that country, which resembles them in some respects, yet the quills of its wings, though very strong in the shafts, have not the peculiar form of these.

SUB-DIVISION V. (*Lampornis*). The birds of this sub-division have the bill considerably arched; and the tail short, sometimes a little rounded, at other times slightly forked, but never very far from being even.

MANGO HUMMING-BIRD (*L. Mango*). This is one of the most common species in the West-India islands, being found in almost all of them; but owing to the changes of plumage to which it is subject at different ages, it has been multiplied into a number of species. This is the more remarkable that the bird itself is more easily observed than almost any of the others, being hardy and familiar as well as common. When full grown its length is about four inches and a quarter; the back, back of the neck, flanks, and lower tail coverts are brilliant golden green; and the forehead and crown, in different lights, exhibit marked and brilliant reflections of the same colour. A stripe of deep velvet black, shaded into the sides with a very bright steel blue, runs from the chin to the vent. A narrow band of white bars the thighs where they join the flank. The feathers of the tail are broad and rounded at the tips; the upper middle feathers are of a beautiful golden green with reflections of violet; the others on the upper part, as well as the under ones, are also of this tinge, but with a deeper hue according as the various lights fall upon them. In the young birds, the plumage on the upper part is of a paler tint, more inclining to a golden brown, while that on the under part is white, mixed with green on the flanks, and having a line of blackish-brown mottling from the chin to the centre of the belly. With the exception of the upper surface of the two middle feathers, which is of the same colour with the back, the tail feathers are pale, but clear violet; and in the very young state the exterior ones have white tips. It is greatly owing to the number of times that these birds breed in the course of the year, and the consequent appearance of individuals in all the varied stages of plumage at the same instant, that so much confusion has been introduced into the popular descriptions of this species; and this shows how necessary it is that we should attend to all the habits and changes of appearance in every animal, of which our knowledge is to be at all correct, even in one particular.

**TOPAZ-THROATED HUMMING-BIRD** (*L. Pella*). This is one of the most beautiful of these birds, and it differs from most others of the sub-divisions in having two produced feathers in the tail, having short and silky webs. Its wings are remarkably sharp pointed; and though the tail, with the exception of the produced feathers to which we have alluded, is rounded, yet it appears that the bird can turn on these feathers, and the sharp points of its wings, much in the same manner that a swallow turns. Its habit also corresponds; for, instead of hovering over flowers as is done by most of the humming-birds, this one is described as beating along the surface of the waters, something in the same style as the martens do, and living upon small-winged insects. It is found in the humid and rich parts of tropical America; and nothing can exceed the splendour of its plumage, as it dashes along over the margins of the streams, or perches on the slender twigs which overhang their banks. It is a bird of considerable size, at least as compared with the other humming birds; for it is five inches and a half in length exclusive of the two produced feathers in the tail, which are fully three inches more. It is exceedingly difficult to say what is the colour of the body, for it is all over one colour, and yet in different positions of the light every part of it is all colours. It is entirely composed of scaly feathers, similar in texture to those which we have noticed as forming the gorgets of so many of the genus; and whenever those feathers occur, we are always certain of obtaining a great variety of colours by exposure to different lights. The unrefracted colour of the body is a sort of brown; but the reflections which it gives out vary from the brightest golden yellow to the most intense ruby red, the former being the prevailing lustre in the under part of the bird, and the latter that in the upper part; while between the one and the other there is a continual play along the sides of the flanks, which has the most beautiful effect that can be imagined. The prevailing colour of the gorget is topaz yellow, which becomes emerald green in oblique lights, deepening towards the extremities, until it passes into a margin of velvet black, which again gradually melts into the general colour of the body. The tail is bright chestnut on the under side, and golden green on the upper, with reflections of bright red. The two produced feathers are purplish black, as are also the quills of the wings. The short feathers of the tail are rounded at the extremity, but the bird has considerable power over the two produced ones, so that it sometimes brings them together at the middle as if they were but one feather, and at other times extends them as if the tail were deeply forked. The tarsi are feathered down to the articulation of the toes; and the feet, though small, are stout and well adapted for perching.

The female is smaller than the male, and differently coloured; the plumage in that sex being green with metallic lustre, but subdued by a greyish tinge. The gorget is much less distinct than in the male bird, and its colours vary from brown to golden yellow. The vent feathers also are grey, the outer tail feathers dull green, the next to them violet, and the remaining ones chestnut colour. The young are without the produced feathers in the tail. They have the plumage above of a bright green colour, marked by blotches of ruby reflections; the under part partakes more of red, and the reflections on it vary from green to orange. The brilliant gorget does not appear

until the birds have arrived at maturity. This singularly beautiful species is rendered a little more perplexing by changes of plumage, to which it is subject in different individuals. These are rare; but they do occur in blotches of pale colour; and when this takes place, the remaining tint is different from that of birds, in which there is no breaking of the colour. Altogether, however, it is one of the most beautiful in the whole multitude of the feathered race.

**WHITE-COLLARED HUMMING-BIRD** (*L. mellivorus*). This species is common in many of the West-India islands, and also in the adjoining parts of the continent of South America. It is fond of low and marshy situations, where it flies low, and has some of the habits of the bee-eaters. The male bird has the forehead, the cheeks, and the ear-coverts, and also the throat, of a very rich blue, the nape and upper part generally golden green, a crescent-shaped spot of pure white on the hind neck, with the points directed toward the eyes, but not reaching them, the space from the gape across the eye being marked by a narrow line of black. The under parts are white, as are also the feathers of the tail, with the exception of the tips, and a narrow portion of the outer margins, and these are black. When the tail is in a state of repose, it is divided into two lobes, curving slightly outwards from each other, and forming a sort of fork, at the extremity of each lobe of which each feather is a little shorter than the one immediately under it, thus showing alternate narrow arches of black and white. When the bird is in action each lobe of the tail expands, but it still retains a slight appearance of being forked. The upper coverts also partake of this forked character, forming two lancet-shaped points of green, which come out very beautifully upon the white feathers under them. In the female the colours are different, the under part being grey; and the green extending to the tips of the middle tail feathers, and over a considerable portion of the basal part of the rest. These last, however, have white tips, and within the white a band of blue separating it from the green. The colours are, however, subject to several variations in the species generally, and more especially in the female; so that they are not so much to be depended on as in many of the other species. The form of the tail is, however, a character which is not easily mistaken.

**BLACK-BREASTED HUMMING-BIRD** (*L. gramineus*). Buffon and some of the earlier describers have named this as if it were a Mexican species, from which it might be concluded that its general habits differ from those which we have just described, and to which it bears a very close resemblance in its structure. They are birds of humid places, and dryness is the prevailing character of Mexico. The name, however, is a mere mistake of the describers; for the bird is found in the West-India islands and the northern parts of South America, where, like the others of the section, it prefers the low and marshy grounds and the margins of the waters. According to Vieillot, it "delights in the vicinity of inhabited places, which it rarely quits as long as the trees and shrubs continue in bloom; it generally perches on a stray or withered twig, where it expands its tail. I have never heard it sing; but while flying, and especially during the season of incubation, it utters a continued cry, which often betrays it before it would otherwise be discovered. This little bird will seldom allow others to approach the tree on which its nest is built. The

mocking-bird is obliged to yield to his pursuit; he continually darts around, and striking his bill at the eyes of the intruder, obliges him to fly." This is rather a stoutly made bird; and though it is not so brilliant as some of the others, it is still a beautiful bird, and one of compact and graceful form, and very powerful wing. There are considerable differences between the plumage of the young and the mature birds; and as the progress from the one to the other is gradual, the young show considerable differences from each other. In the full-grown male, the upper part is golden green; and the gorget on the throat and fore neck fine emerald green, and composed of very handsome scale-shaped feathers, which are very changeable in different lights, and even black, when no portion of refracted light from them reaches the eye. Immediately under the gorget there is a patch of dull purplish black on the breast, gradually passing into the green colour of the upper part, and backwards, and on the flanks passes into brown, while the vent feathers are white. The tail is large and strong, rounded at the extremity, and black at the tip; but the feathers are purplish brown for more than two-thirds of their length. In the young, the upper part of the body is golden green, as in the mature birds; but the green gorget on the neck is wanting; and the whole of that part, as well as the middle of the under part generally, is dull black. This black is more or less broken at the sides, as is also the green on the upper part, and the space between is of a dull whitish colour, with blotches of red brown and green blended together. The middle tail feathers at this age are deep oil-green, and the remaining ones, with the exception of a white spot on the extremity of each, are very like the same feathers on the mature bird.

**GREEN HUMMING-BIRD** (*L. viridis*). This species occurs in some of the West-India islands. It is not so striking in its plumage, but still it is a very pretty little bird. The whole colour of the plumage is an emerald green, with very little metallic reflections except on the upper tail coverts. The tail is bluish black, with a narrow white margin on the outside of each of the exterior feathers. It is rather a rare species, and few specimens have been brought to Europe.

**BUFFON'S HUMMING-BIRD** (*L. Buffonii*). This is a handsome species, though very little is known respecting it, not even what country it inhabits; but it is supposed to be Brazil. That country, however, becomes a sort of Siberia to all humming-birds of which the localities are imperfectly known; for just as it has been the custom with the describers of migrant birds of the eastern continent to send to Siberia every bird for which they could find no resting place, so it has been very much the custom with those who have attempted to describe the appearances and localities of humming birds, to refer to Brazil every one of whose native country they were ignorant. This bird has the whole clothing feathers, with the exception of those on the vent, between the shoulders, and in the middle of the belly, of the scaly character. The general colour is golden green, passing into brownish green in some parts, and into emerald green in others, while on the under part the tint is more inclined to blue; and the edges of the feathers are relieved by greyish margins. The under covert of the tail and vent feathers are white, the tail feathers themselves are blackish blue, and the quills are purplish black. The bird is stoutly made, and between five and six

inches in length; and altogether of a more robust appearance than very many of the genus.

**PURPLE HUMMING-BIRD** (*L. Caligna*). In its size and form this species bears a considerable resemblance to the last-mentioned; but the form of the bill is different, being almost entirely straight, while that of the others is slightly bent. The only specimens which have been examined are understood to have been natives of Mexico, or at all events to have been procured from that country. They have, however, been few in number, and the bird is consequently very rare; because if it were even moderately abundant, its beauty, and the peculiar tint of its plumage, in which it differs from every other known species, would make it sought after with avidity. Rare as it is, however, there is no good reason for supposing that the specimens which have been obtained are coloured varieties of any other better known species, for the general air and character of the bird are as distinct as the tints of its colour. The general plumage is purple, varying on the upper part from pure violet to a very intense and brilliant red, according to the light in which it is seen; and subdued on the under part with a mixture of a very delicate grey, which is really more beautiful than many of the colours that are gayer and more decided in the tint. The colour on the upper part passes from the purple gradually to golden green on the lower part of the back, the rump, and the upper coverts of the tail, with the exception of the last coverts, on which again the purple is predominant. All the feathers on the upper part, from the base of the bill to the tail coverts, are of the scaly character; and they increase in size toward the tail. They have metallic reflections of rich lustre throughout the whole extent, but those reflections rather increase in brilliance as the feathers become larger; and some of those toward the hinder part show golden yellow and golden green on the margins, and purple on the centre; the gorget is formed of delicate grey feathers, darker in the centre; the colour of the whole under part is particularly soft and pleasant, and passes nearly into white on the vent feathers; the tail feathers are strong and broad, and shortest in the middle, making a slight fork, or rather two lobes with curved extremities; they are of the same purplish colour as the upper part, and so also are the quills of the wings, but they are without the brilliant reflections; the larger coverts of the wings are of the same purple mixed with green, and the green increases in those which are nearest the body. Altogether, however, there is much less green in this bird than in almost any other of the family.

**BLACK HUMMING-BIRD** (*L. niger*). is another species, remarkable for the peculiarity of its colour. The prevailing tint is deep black, dashed with a tinge of blue on the head, and of green on the upper part of the back, and the scapulars. The vent and tail feathers are white, but the latter have a band of black across the tips. The female has the general colour much less intense, and inclining to brown; and the tail is black, with the exception of the outer web of each of the exterior feathers. This is a Brazilian species, but it is not very common.

There are various other species of this, as well as of the other sub-divisions, which are met with in extensive collections of these singular birds; and there is no doubt that in proportion as the tropical parts of America are more explored—and the exploring of them has now become practicable, and is for other

reasons desirable—many more will be added to the lists, and something known of their manners beyond what we understand at present, which, it must be supposed, lies within a very small compass. The account which we have given is little else than a mere catalogue; and we have not been able to say much of their relations to the rest of nature, but it is all that our limits will afford.

**HUMULUS** (Linnæus). A genus of plants. The *H. lupulus* is the well known hop, a British plant, but extensively cultivated for its use in manufacture of beer and porter. The hop belongs to the order *Urticæ*. The specific denomination *Lupulus* is a corruption of the old name *Lupus salictarius*, the willow wolf, as we are informed by Pliny it formerly was called on account of its growing amongst osiers, to which, by twining round, overbearing, and choking them, it becomes as destructive as the wolf to the flock. Our English name, hop, evidently comes from the Anglo-Saxon *hoppian*, to climb, and it is admirably descriptive of the habit of the plant.

Above fifty thousand acres in Kent, Sussex, and Hereford, are estimated to be already in existence. The duty on hops, with the uncertainty of the crops, often raises them to an extravagant price; hence the temptation is great to substitute some other bitter for the hop. This is, however, resisted by the excise as a fraud on the revenue, but still more vehemently resented by the public, who will tolerate, in theory, no brewing save from genuine malt and hops. The young shoots of the hop, blanched, are sometimes eaten as asparagus, for which they form an excellent substitute. From the bines a coarse sacking has been made, and a yellow dye extracted.

**HURA** (Linnæus). A genus of South American trees, called by the English sandbox-trees. They belong to the order *Euphorbiaceæ*. They receive the specific names, *Strepens* and *Crepitans*, from the noise which is made by the elastic bursting of their capsules. The sap contains, like that of the *Excoecaria* and other *Euphorbiaceæ*, caoutchouc, and is very acrid.

**HUTCHINSIA** (R. Brown). Annual and perennial herbs, natives of Europe, formerly ranked with the *Lepidium* and *Iberis*, closely allied genera all belonging to *Crucifera*.

**HYACINTH** (Linnæus). A beautiful and much esteemed bulbous bed-flower, belonging to the sixth class of Linnæus, and natural order *Asphodeliæ*. This genus has been long celebrated, not only for the beautiful fable whence its name has been fancifully derived, but also for the immense number of varieties which culture has produced. Of the *H. orientalis*, the common species, the Haarlem florists had at one time upwards of two thousand varieties. These bulbs, as well as those of the tulip and narcissus, once formed a most valuable, and still a not important, branch of Dutch commerce.

**HYACINTH**. This beautiful mineral was well known to the ancients, who applied the same name to common zircon, when it partook of the hyacinth-red colour. It occasionally occurs in angular grains, but is more frequently crystallised, of which two examples are given in the annexed diagrams.

Hyacinth may readily be distinguished from the garnet by its crystallisation, resinous lustre, distinct cleavage, and great weight. It occurs in every quarter of the globe, but some of the finest specimens have been brought from the Island of Ceylon. This stone readily loses its colour when exposed to the

action of heat, and, in consequence of its great brilliancy, it is frequently substituted for the diamond,

Hyacinth.

the colour being first destroyed by the action of the blowpipe. It is, however, rarely found of a large size. Small crystals of quartz, tinged with iron, are found in Spain, and have been termed "Hyacinths of Compostella."

**HYALÆA** (Lamarec; *ANOMIA TRIDINTATA*, Linnæus). This very extraordinary mollusc is of a thin transparent horn-like substance, differing in that respect from the common character of shells as they are generally understood. Its form is tricuspidated, with hollow points, and finely striated transversely. The valves are united, or, as it may familiarly be termed, soldered together. They are unequal; one being sub-globular, ventricose, and anteriorly shortened, occasioning an aperture through which the animal protrudes the two wing-shaped portions of its body; the other is larger, and has its under part nearly flat. It has been fancifully called the Chariot of Venus, from some resemblance it bears to the form of a triumphal car in miniature; and it has been asserted that these molluscs have been seen sailing before the breeze in little fleets; that fact does not, however, rest upon corroborating evidence, though the substance of these molluscs render them peculiarly fitted for such an exhibition, should it be hereafter ascertained, by more frequent observation, that such is the animal's habit of locomotion. Five or six species have been described, all of them inhabiting the warm latitudes; and the genus *Glandiolus*, of D. Montfort, is nearly allied to it in its general characteristics.

**HYDATICUS** (Leach). A genus of coleopterous insects, belonging to the family of the predaceous water-beetles (*Dyticidæ*) of a moderate size, having the anterior tarsi dilated into a rounded patelliform plate, the elytra smooth in both sexes, and the third and fourth joints of the maxillary palpi of nearly equal length. There are four British species, all of which are of rare occurrence, the type being the *Dyt. transversalis*, Fabricius. In their habits they do not differ from the larger *Dyticidæ*.

**HYDRÆNA** (Kugellan). A curious genus of minute coleopterous insects, belonging to the *Rhyphagous* water-beetles, and family *Helophoridae*, having the maxillary palpi three times as long as the antennæ, by which character they are distinguished from the remainder of the family. The species are found at the roots of grass growing upon the margins of standing water and streams. Their legs are not formed for swimming, and they creep but slowly. Mr. George Waterhouse has lately published a valuable

Spotted Hyena

Spotted Hyena

Spotted Hyena

monograph upon this genus in the Entomological Magazine.

**HYDRANGÆA** (Linnæus). A genus of deciduous shrubs from North America, but the greatest favourite of the genus is the *H. hortensis*, introduced into our gardens from China about 1788. They belong to the tenth class of Linnæus, and to the natural order *Saxifragææ*. One of the peculiarities of the Chinese hydrangæa is its change of colour of the flowers. In common soil they are pink; but, if kept for a season or two in peat earth, they become blue.

**HYDROCAMPÆA** (Latreille). A genus of Lepidopterous insects, belonging to the section *Nocturna*, or moths and family *Pyrætidæ*, having the spiral tongue distinct, but differing from *Botys* and the other genera belonging to the same family by the aquatic habits of the larva, (whence the generic name signifying water-caterpillars) and by the structure of the insect in this state enabling it to reside in such a situation. We know scarcely any circumstance more interesting in zoological physiology than that a small assemblage of insects, like the present, should be so completely modified in their preparatory structure as to be able to reside in an element which would be certain death to the caterpillars of every other lepidopterous insect. In the larvæ state, these insects feed upon the leaves of aquatic plants, such as pond weed, potamogeton, &c.; and Reaumur has given us an account of the proceedings of one of these insects, observed by him in the Bois du Boulogne, on the under surface of the floating leaves of the last-named plant, and inhabiting a little moveable nest, formed out of the leaves of the same plant with considerable mechanical nicety. Piercing the leaf with its jaws and gradually gnawing a curved line, it cuts off a morsel of the leaf of the size and shape adapted to its wants, which it at first slightly attaches by silken threads to the under surface of the main-leaf, leaving intervals between them through which it may protrude its head. The piece already cut serves as a model for a second piece, which it affixes accurately to the former with silk, forming an oval, but within which it introduces its body, retaining its situation by means of the fleshy legs at the hinder part of its body, and which it carries about with it from place to place, using its fore legs, which with its head it thrusts out of the aperture left at one end. When, however, it would form a cocoon, in which to undergo its transformations, it uses but a single piece, which it attaches more firmly than before, its under surface being applied to the under surface of the main leaf, on account of the under side of the leaf being concave, by which means a hollow cell is produced, although the edges are firmly united. Within this tent it then spins a regular silken cocoon, which is, of course, secure from the water, being defended by its outer leafy covering; and in this position it is soon transformed to a chrysalis, appearing again only when it has become a perfect insect. The caterpillar is of a long and fleshy form, its sides being furnished with several long and slender filaments, laterally attached to each segment, and which are employed as external gills for imbibing air from the water. The pupa is also furnished with three pairs of large spiracles placed on the three basal joints of the abdomen. These spiracles are of a totally different construction from the gills of the larvæ, being serviceable only for respiring air; for the caterpillar has the power not only of rendering its cocoon water-proof, but also of forming it without any water being

introduced. Still, as if proving that the transition from a watery to an aerial mode of respiration was not yet effected, De Geer, who studied the insects with great care, ascertained that it was absolutely necessary that the cocoons should be kept under water, as the chrysalides died on being removed into the open air. When the time of its last transformation is arrived, the moth, still with its wings unfolded, emerges from its cocoon, creeps up the stems of the plant, and appears in the air, in which alone it can now live. There are several British species of these moths, to which, from the elegant markings of their wings, collectors have given the names of China marks. Some of them are sufficiently common, and may be found during the summer months upon aquatic plants. The type of the genus is the *Phalæna Potamogota* of Linnæus.

**HYDROCHARIDÆÆ**, a small natural order of plants, comprising as yet only four genera, viz., *Vallisneria*, *Hydrocharis*, *Damasonium*, and *Stratiotes*, which are all aquatics. The lilyfrog-bit, *Hydrocharis*, and the water-soldier, *Stratiotes*, with the interesting *Vallisneria* and *Damasonium*, form collectively the order as above. They are distinguished from each other, as will be seen by the generic characters given under their names respectively.

**HYDROCHARIS** (Linnæus). A British aquatic herb, commonly called frog-bit or bite: class *Diœcia*, and natural order *Hydrocharidææ*. Generic character: flowers *Diœcious*, calyx of three sepals, bracteate, and coloured. Petals three, inversely egg-shaped. Stamens triple, inserted on the abortive style; stigmas three, filiform, united to the inside of the stamens. Anthers roundish, bursting all round. In the female flowers, the styles are six, two-parted, with abortive filaments. Capsule six-celled, and many seeded. This plant is often met with in wet ditches.

**HYDROCORISA** (Latreille). A primary section of hemipterous insects, comprising such species as reside in the water, and which differ from the *Geocoris*, or land-bugs, by having the antennæ minute and inserted beneath the eyes. They are predaceous in their habits, feeding upon other insects, which they seize by means of their fore legs, which serve as claws, the extremities folding upon the basal portions. The section comprises two families, the *Nepidææ* or water-scorpions, so named from the chitiferous structure of the fore legs; and the *Notonectidææ*, or boat-flies, so named from the boat-like form of the body and the oar-like structure of the hind legs.

**HYDROCOTYLE** (Linnæus). A genus of aquatic herbs, occurring in many parts of the world. One is common in Britain, and known by the name of pennywort. The genus is only interesting to botanists, by whom it is placed in *Umbellifereæ*.

**HYDROLEACEÆ**. A natural order of plants, containing a single genus only, of which there are two species. They are little elegant plants with blue flowers, chiefly distinguished from *Convolvulacææ* and *Polemonacææ*, in the flowers having two styles, as well as in the two-valved capsules. The leaves are alternate and simple, entire or lobed, and without stipules.

**HYDROMETRIDÆÆ** (Leach). A family of hemipterous insects, belonging to the section *Heteroptera*, and sub-section *Geocoris*, and affording an instance of the great difficulty attending the natural classification of groups in natural history. From the structure of the antennæ and proboscis, these insects are united with the land-bugs; but in their habits

and the structure of their legs, formed for aquatic life, they are more properly *Hydrocorisæ*, from which, however, they differ in residing upon the surface, and not in the water. For this purpose it is necessary that they should be defended against the action of the waves in the most complete manner, and which we find effected in a two-fold manner. In the typical genus, *Hydrometra*, the legs are simply formed for walking, but the insect is considerably elevated by them above the surface, and is enabled easily in this manner to make its way through grass and the stems of plants growing at the edges of ponds, &c., which is its proper locality; whereas the other genera (*Gerris*, *Velia*) rest their bodies upon the surface of the water, but they are defended from its action by a coating of silky hair, over which the water glides without affecting the body of the insect—these, moreover, are provided with long rowing legs, which enable them to skim rapidly along the surface of the water. The genus *Hydrometra* is extremely slender, and the head is produced into a long, narrow muzzle. The type is the *Hydrometra stagnorum*, which is an opaque black colour, and more than half an inch in length. For the characters, &c. of *GERRIS*, see the article upon that genus.

**HYDROMYS.** A genus of rodent mammalia, hitherto found only in the southern part of Australia, and we believe only in Van Diemen's Land. They are remarkable among the mammalia of that country in not being marsupial. As they have been hitherto seen on the south coast of Van Diemen's Land only, it is possible that they may be importations which have been brought there by visitors from some other part of the world, whose appearance has been forgotten by a race so totally without historic recollections, and so prone to extirpate any strangers that come among them, as the original inhabitants of that island unquestionably are. Though these animals are called hydromys, or water mice, they do not exactly agree with our water mice, nor with those of any other part of the world; they are characterised by having five toes on each of the feet, all free on the fore feet, and webbed on the hind ones; all the toes are furnished with claws, which are small and pointed, except that on the thumb of the fore foot, which is flattened, and the thumb itself is but little produced; their teeth are also peculiar; they have only twelve altogether, namely two incisors, and four cheek teeth in each jaw; the upper incisors are united and flat in their anterior surfaces, and the same surface of the lower ones is rounded; the first grinder in the upper jaw is always longer than the second, and the crown of the first is composed of three, and that of the second of two depressions, surrounded by elevated portions of enamel; the two in the under jaw are formed in nearly a similar manner, and the first one is double the size of the second. This system of teeth is among the most simple which is met with among mammalia, excepting in those species which are reckoned toothless; the ears are very short, and rounded; the tail is round, and covered with short hair; the body is covered with two sorts of hair, one woolly and very soft to the feel, and another much longer and thicker in the single hair, and shining and silky in appearance. Their covering thus makes a slight approximation toward that of the South Sea seals, which are so abundant in the offing of the places where the present genera are found on the shores. Only two species have been described, and it is not very well

ascertained whether these ought to stand as distinct species, or only as varieties, though the former is perhaps the more correct view of them. These species are distinguished as *Leucogaster*, or white belly and *Crysogaster*, or yellow belly.

The first has the body about a foot in length, and the tail about eleven inches. All the upper part is brown, and the under part, which is also the colour of the distal half of the tail. In this one, the hind feet have webs for only half the length of the toes, which would indicate an animal of not absolutely aquatic habits. The fur all over it is very soft and delicate to the touch.

The other species is nearly of the same size, and differs from it chiefly in the colour of the belly, and that of the tail, which has only the tip white. The fur upon this last mentioned one is also considerably finer than that upon the other; but enough is not known of them for warranting us to say positively whether they are, or are not, separate species. The places where they have been seen, have been chiefly, if not exclusively, the small islands which lie in the entrances to the river Derwent, and render those entrances so dangerous to shipping. It is supposed that they are not numerous; and we have mentioned that they may be foreigners; and the chief point of interest about them is, that they stand almost alone as placental mammalia, in a country where all the rest are marsupial, with the exception of the dog; and we have endeavoured to show in the article Dog that the dingo, or wild dog of Australia, is an importation by the Malays. The curious fact of the animals of Australia, in both of its islands, being almost as exclusively marsupial as those of the rest of the world are placental; and the connexion which this has with the singular physical nature of the country are, however, points which we cannot decide without much more information than we are in possession of at present.

**HYDROPELTIDÆ.** A natural order of plants, comprising a single genus, of which there is only one species described; but of the properties there is nothing certain known. *Hydropeltis* is an aquatic, and intimately connected with *Caltha*; and a kindred genus, called *Cabomba*, bears a great similitude to the *Batrachia*, even in its heteromorphoses foliage; the floating leaves being lobed, while the immersed ones are very much divided. De Candolle mentions their affinity to the *Nymphæaceæ*, with which they are associated by Bartling.

**HYDROPHILIDÆ** (Leach). A family of coleopterous insects, belonging to the section *Pentamera*, and division *Rypophaga* of Stephens (*Philhyrida* Mac Leay), comprising such species of water-beetles as have the antennæ short and clubbed at the extremity, and the palpi long and slender; the mandibles are bidentate at the tips, the body is oval and convex, and the hind legs often ciliated. Like the *Dytiscidæ*, which also inhabit the water, these insects exhibit but little variation in their colours, which are ordinarily obscure. The consistence of their bodies is firm, and they are often armed with a strong acute spine, which extends between their hind legs. They are furnished with wings, whereby they are able to transport themselves from one piece of water to another, when they are so inclined. Their motions in the water are much less active than those of the *Dytiscidæ*, the legs not being moved simultaneously. This want of agility is dependant in a great measure

upon the nature of their food, which consists of vegetable matter, although it has been stated that they will also feed upon small aquatic mollusca and insects; but this observation was made by M. Miger upon insects in a state of captivity. M. Esper has made another observation, which shews the weakness of these insects when compared with the other water-beetles. He had confined an individual of the largest species of this family, *Hydrous piceus*, in a glass of water with a *Dytiscus marginalis*, not more than half of its size the former, nevertheless, fell an easy prey to the latter; which, having detected a vulnerable part between the head and thorax, greedily devoured it. Unlike the *Dyticidae*, these insects exhibit a great degree of care for the preservation of their race, in the manner in which they deposit their eggs; which, instead of being laid at random in the water, are united into a mass, and enclosed in a silken cover, in which they are carried about by the female beneath her body until she is able to meet with a convenient spot for their reception, and which is ordinarily the stem of some aquatic plant upon which she attaches her mass of eggs above the surface of the water, whereby they are defended from the attacks of her enemies; in this situation the eggs hatch, and the young larvæ fall into the water. Such is the mode adopted by the smaller species; but the larger ones (*Hyd. piceus*, &c.) differ somewhat. Like the former they are provided with spinnerets at the extremity of the body, and they spin a bag of pure white silk, of a very large size, having on one side an elevated twig or branch, in which the eggs, to the number of fifty or sixty, are enclosed in an upright position, and it is not until they have been hatched several hours, that the young larvæ make their escape. It appears, moreover, from the recently published researches of Lyonnet, that the female also employs in the construction of her nest the fibres of aquatic plants. This, however, is contrary to the remarks of M. Miger; who informs us that the use of the elevated branch of the nest, and which is raised above the surface of the water, as it floats about, is of service in conveying air into the mass of eggs enclosed in the nest. The larvæ are large fleshy grubs, furnished with six legs, which, as well as the head, are of a scaly nature; the former being of a curious form, nearly flat above, and rounded below, which gives it the appearance of being turned upside down. They respire by the assistance of two slender appendages at the extremity of the body. When arrived at its full size, the larva quits the water, and burrows into the soft adjacent earth, where it forms a cell, having the inside smoothened, and in which it becomes a pupa, not exceeding one-half of its previous length; the larva of *H. piceus* being three inches long, and the pupa only one and a half. The abdominal segments of the pupa are furnished with long lateral filaments or soft spines; its thorax is also armed with three curved spines on each side. By these, and by the appendages at the extremity of the body, the pupa is stated to be raised from the surface of the cell, whereby it is prevented from being in constant contact with the damp earth. On arriving at the perfect state, the insect again seeks the water, in which it constantly resides, but it is necessary that it should come from time to time to the surface to obtain a supply of fresh air. Authors had remarked that at such times, unlike the *Dyticidae*, which respire by the extremity of the body, it protruded its antennæ out of the water, and that they

were applied against the body when it retired again below the surface: but the recent observations of M. Audouin have shewn, that it was by this motion that a bubble of air is carried along the under side of the thorax until it arrives at the abdominal spiracles. The majority of these insects are of small size, but the family comprises a few species, which are amongst the largest of the aquatic coleoptera. The genera are, *Hydrophilus*, *Hydrous*, *Philhydrus*, *Tropisternus*, *Sternolophus*, *Hydrobius*, *Volvalus*, *Berosus*, and *Limnebius*; to which Mr. Stephens adds *Spercheus*. In the typical genus, *Hydrophilus*, the sternum is spined, the pectoral carina being bifid, and the antennæ are obtuse at the tips. The type is the *Hydr. Caraboides*, Linnæus, a very common species, found in the stagnant ponds and ditches, being about three-quarters of an inch in length, and of a shining black colour.

**HYDROPHYLLEÆ.** A natural order of elegant herbaceous plants, natives of North America. The order contains five genera, viz. *Hydrophyllum*, *Phacelia*, *Eutoca*, *Farronia*, *Nemophila*, and *Ellisia*. These associated genera very closely resemble the *Boraginideæ* and *Heliotropideæ*: the twin-celled basal nectary, and one-celled ovary, will, however, sufficiently distinguish them. The fungous-stalked *Placenta* is also a very peculiar and characteristic structure.

**HYDROUS**, (Linnæus). A genus of pentamerous coleopterous insects, belonging to the family *Hydrophilideæ*, and differing from *Hydrophilus*, in having the antennæ acute at the tips, the pectoral carina of the prosternum simple, and the terminal joint of the male tarsi, which is dilated into a large triangular plate. The type, *H. piceus*, is the largest of our British water-beetles, being an inch and a half long, of an olive black and shining colour. It is found in ponds and stagnant waters, but not very commonly.

**HYDRUS** (*Hydra*). A genus or rather family of serpents, which are all inhabitants of the seas or rivers of warm countries. The name was originally applied allegorically to a monster which Hercules is fabled to have subdued; and though Linnæus transferred the name to one of the simplest of all animals, an inhabitant of the fresh waters which can be multiplied by dividing the body into segments, those who treat of the natural history of serpents very generally apply it as the distinctive name of water-serpents, whether these happen to be poisonous or not. They are found in greatest abundance in the seas and rivers of the south-east of Asia, of Australia, and of some of the adjoining countries. In their teeth they resemble the *Colubres* and *Acrocordi*, but they have generally a smaller number of teeth in the external range; and some have the first of this row on each side much larger than the others, and perforated for the purpose of conveying their poison, which is of a very deadly nature in some of the species, into the wound inflicted by the tooth. They live generally under the water; and in this they are distinguished from some other species which are often found swimming on the surface, but which seldom or never dive to the bottom, as the true hydras are in the habit of doing. They feed almost exclusively upon fish. Some of them grow to a very large size; and many, indeed the greater part, are remarkable for the brilliance of their colours and the elegance of their markings. Cuvier divides them into three subgenera:—

*Hydrophis*, which chiefly infest the seas, rivers, and other waters of Bengal and the adjoining countries.

They usually remain quiet at the bottom, or buried in the sand, during the day; but at night they come to the banks, and attack land animals, and even human beings when they resort to the waters for the purpose of bathing, washing, and cooling themselves. Their characters are: a row of scales along the belly, larger than those on the rest of the body; the head small, obtuse, and furnished with large plates. There are many species of them, some poisonous and others not; but the whole of them are to be regarded with suspicion. The body is compressed in the posterior part, and well adapted for making way through the water.

*Pelamis*. These have the head covered with large plates as in the former subgenus; but they differ from it in having the occiput tumified in consequence of the length of the pedicles of the lower jaw, which allow a very large opening to the mouth, something in the manner of the pythons, boas, and other large serpents which kill their prey by crushing it. All the scales on the body are nearly equal in size, and they are arranged like a sort of pavement. The greater number of them are found in the tropical and southern Pacific, in many parts of which they are very abundant, and grow to a large size. The natives of some of the islands in that sea eat their flesh when they can capture them.

*Chersydrus* have the scales upon the head and body nearly of the same size, without any large plates upon the head. They are chiefly found in the seas and rivers of Java, where some of them are possessed of very deadly poison. By some writers they have been confounded with serpents which are perfectly harmless, as well as singular; and those mistakes are the more to be regretted, when a perfectly harmless animal is confounded with one whose powers of doing mischief are very great. Thus *Aular cærrau* of the Javise, *Acrochordus Javanensis*, or warty serpent, is not only not poisonous, but a vegetable feeder; while the *Aular limpe*, which is the banded *Acrochordus* of some authors, is perhaps the most poisonous serpent that inhabits the water. The history of the whole race is imperfect however; and, from the difficulty of obtaining information, it is not easily rectified.

**HYLÆUS** (Fabricius). A genus of short-tongued bees (*Andrenidæ*), which see for its characters.

**HYLOBIUS** (Germar). A very destructive genus of coleopterous insects belonging to the section *Tetramera* and family *Curculionidæ*, having the antennæ twelve-jointed, the rostrum moderately long, somewhat rounded with a lateral impression extending from the middle of the eyes; the elytra, which are not united together, are of an oblong-ovate form, and the body is furnished with wings; the legs are moderately short and thick, and the femora are armed with a spine. There are several species, one only of which has fortunately occurred in any abundance in this country. This is the *Curculio abietis*, Linnæus, a species varying from five to nine lines in length, of a pitchy black colour, with numerous yellow spots on the elytra. This insect has rarely occurred in England, but in Scotland it has been found in great quantities in the fir plantations, in which it makes great devastation, as appears from a letter from J. Loch, Esq., agent for the estates of the Marquis of Stafford and Earl of Carlisle, dated August 29, 1824, and addressed to Mr. W. S. MacLeay, by whom it was published in the fourth number of the *Zoological Journal*:—"There has been lately a great failure of the young firs and larches on Lord

Carlisle's estates here. It was at first thought to be occasioned by mice, so completely was the bark destroyed. The wood-warden is now, however, persuaded that the mischief is done by the insects inclosed in the box sent along with this. The destruction is more rapid where the roots of the Scotch fir are in a state of decay." Mr. MacLeay then proceeds—"This last remark indeed goes of itself far to prove that the author of the mischief is an insect, for mice would only attack the green and healthy bark; and to set the question at rest, the insect of which many specimens were sent, proved to be no other than the *Hylobius abietis* of Germar (*Curculio pini* of the *Entomologia Britannica*), an insect most destructive to firs. It is very common in the pine forests of Sweden and Scotland, but in England I believe it has only as yet been found in Cumberland and Shropshire." Mr. MacLeay then gives the synonymy of the insect, which Linnæus named *Curculio pini* as well as *C. abietis*, observing that it inhabits the *Pinus sylvestris*, and devours its resin; and then, in his peculiar style, he proceeds to describe its manners as follows:—"Tarde incedit, arcte apprehendit, tenaciter adhæret, ore frustra cutem mordere tentat captivum." Beyond these observation little is known of the economy of this destructive insect, and it is therefore impossible to point out a remedy for the evil until we have more detailed accounts of the method in which the trees are attacked. The naturalists in the north might, however, easily acquire some insight into the history of the insect, by examining the fir trees in Rivelston Wood, near Edinburgh, where it was first discovered during the winter season, and watching the larvæ until they make their appearance as perfect insects.

**HYLURGUS** (Latreille). A genus of coleopterous insects belonging to the section *Tetramera*, and family *Scolytidæ* (or *Bostrichidæ*, which see), having the elytra rounded at the tips, the thorax not hooded, the club of the antennæ sub-globose, and the body cylindrical. These are small beetles of very destructive habits, the type of which (*Dermestes piniperdus*, Linnæus) is figured in our first volume, p. 570, col. 2, where fig. 3 represents the insect of the natural size, fig. 4 ditto magnified, fig. 5 the larva or maggot, and fig. 6 the pupa (the figures 1 and 2, of which the names were accidentally omitted, represent the typographer beetle of the natural size and magnified, of whose proceedings an account is given in the preceding page). The pine *Hylurgus* is extremely injurious to young pines, by destroying the leading shoots. The following observations respecting it were made by Professor Lindley, and communicated to Mr. Curtis, with drawings of the sections of the stems shewing the course of the tracks of the beetle:—"For the purpose of examining its proceedings more narrowly, I placed a shoot of the Scotch fir under a glass with the insect. In about three hours after, it had just begun to pierce the bark at the base of one of the leaves; its mandibles seemed chiefly employed, its legs being merely used as a means of fixing itself more firmly. Four hours after, its head and thorax were completely buried in the shoot, and it had thrown out a quantity of wood which it had reduced to a powder, and which nearly covered the bottom of the glass. In sixteen hours more it was entirely concealed, and was beginning to form its perpendicular excavation, and was busily employed in throwing back the wood as it proceeded in destroying it; there were evidently two kinds of this saw-dust, part consisting

of shapeless lumps, but the greater portion of very thin semi-transparent lamellæ, or rather shavings. I now examined it every day till the fifth, when I found it had emerged through the central buds at about an inch from where it had first commenced." This species is about one-sixth of an inch long, of a black colour, with the elytra finely punctured in lines; it varies to a pale dirty buff or red colour, probably owing to immaturity. There are numerous other species of this genus, eight being inhabitants of this country.

**HYMENŒA** (Linneus). A genus of plants, called from its having united leaves. They are the locust trees of English travellers, and found in tropical America and Madagascar. The flowers are decandrous, and of course belong to the natural order *Leguminosæ*. The pods of *H. courbaril* contain a soft filamentous substance as sweet as honey, and having an aromatic flavour something resembling gingerbread. The Indians are extremely fond of the fruit, and the monkeys, as well as the children, devour it with avidity. The gum known in commerce as *gum animi* is extracted from several of the species. The heartwood of the courbaril is very hard and tough, and is hence much valued for wheel work, particularly for cogs. It will take a fine polish, and is so heavy that a cubic foot weighs about one hundred pounds. It is called "mountain ebony." In our stove-collections the plants are grown in loam and moor-earth, and increased by cuttings.

**HYMENOPTERA**. An order of insects belonging to the great division *Mandibulata*, or those furnished with lateral jaws, and distinguished by having four membranous wings, furnished with various veins, forming cells, but not assuming the appearance of net work, the posterior pair being smaller than the anterior; the mouth composed of a pair of upper and lower jaws, and two lips, the lower of which is elongated, and forms, together with the lower jaws, a kind of tongue or sucker, capable of being extended to a considerable length, and employed in collecting honey from flowers; the females are furnished with a horny apparatus, at the extremity of the body, which in some species is transformed into a pair of saws, adapted for making slits in twigs of plants, for the reception of the eggs, and in the others consisting of a powerful sting, the structure of which we have already described in our article upon the bee. In others again, it is elongated into an ovipositor, adapted for depositing the eggs in the bodies of caterpillars, &c. The head is furnished, moreover, with a pair of antennæ, which in the typical division, consist of thirteen joints in the males, and twelve in the females; in the rest the number of the joints varies in the greatest degree, in some consisting of only five or six, and in others of sixty or seventy articulations. In the form of these organs we also find great variation, the sexes differing in this respect, in some being long and slender, in others short and clubbed; in some furnished with hairs, in others branched or forked, and in the majority elbowed at the extremity of the basal joint, which is ordinarily long. The eyes are large, and occupy the sides of the head; they are alike in both sexes, except in a very few instances, in which they are united in the males on the crown of the head, as in some of the diptera, they are generally round or oval, whilst in some, as the wasps, they are kidney shaped. They are asserted to be obsolete in a few species of ants.

In addition to these composite eyes, the majority of the insects of this order are furnished with three minute simple eyelets (ocelli), on the crown of the head; the lower jaw and lip are furnished with palpi, which vary in the number of their joints from six to one.

The thoracic segments are united into an oval mass, in the front of which is to be observed an arched piece, termed the collar; and at the sides are attached the two pairs of wings, the anterior pair having a scale (squamula) at the base. The front margin of the anterior wings is furnished, a little beyond the centre, with a callous point, termed the stigma, *c*, from which is emitted a vein or nerve, which runs to the tip of the wing, the space between it and the front margin of the wings forming one or two cells, which are termed the marginal or radial cells, *a*, behind this nerve, and running somewhat parallel with it, is another nerve connected with the former by various short transverse nerves, the space between which forms the submarginal or cubital cells, *b b b b*, varying in number from one to four; there are other nerves forming basal and discoidal cells, but the former are of the greatest importance, being employed as affording constant characters in the discrimination of genera. There is, perhaps, nothing more strikingly calculated to prove the beautiful order and certainty existing throughout nature, than is exhibited by these slender and apparently trivial nerves, which maintain their position in every individual of a given species, although in the adjacent species the situation of some one or other of them may be altered. Of such importance, however, is the consideration of these nerves, that in the latest work upon the Hymenoptera (St. Fargeau, Hist. Nat. des Ins. Hymenopt. Paris, 1836.) we find upwards of five and twenty pages devoted to their illustration. We have here represented the an-

terior wing of gorytes, in which we have a number of cells; but in some groups the number of the nerves is greatly diminished, and in few, as the Chalcididæ and Proctotrupidæ, the nerves are almost, and even absolutely and entirely, obliterated. In many of these insects, a remarkable apparatus exists, whereby the two wings on each side are kept steady together in flight, consisting of a series of very minute hooks or crotchets discoverable under a good magnifier on the anterior margin of the posterior wings. They have been noticed by no other authors than De Geer and Kirby, the latter of whom observes, that they are much more conspicuous in the bees than in the winged ants. The legs, which are six in number, are inserted on the lower side of the thorax, and consist of various pieces, which contribute to their movements. These pieces are the *coxa*, a short piece connecting the leg with the thorax, *trochanter*, another short piece articulated between the coxa and the following piece, and which in the ichneumonidæ, is divided into two parts; the femur, or thigh, which is long and

robust; the ibia, or shank, which is more slender, and terminated by one or two spurs; and the articulated tarsus, which constantly consists of five joints, the fifth being of a conical form, the extremity being the thickest part, and furnished with two strong but small claws, between which the pulvilli, or cushions, are often to be observed. These legs, which are, in fact, the chief organs whereby the insects are enabled to carry on their varied economy and habits, are necessarily very varied in their form, and in the appendages with which they are furnished. The abdomen, which is also of a very varied form, is attached to the posterior part of the thorax, either by its entire width, in which case it is said to be sessile, or by means of a slender peduncle, or foot-stalk, which in some groups is also long as the abdomen itself. At the extremity of this abdomen, on its lower surface, is attached the ovipositor, saw, or sting above mentioned, each of which, although varied in form, so as to suit its intended uses, is but a modification of the same instrument. From the centre of the underside of the abdomen, near its extremity, arise two plates, each consisting of two joints, sometimes valvular, and together forming a scabbard, sometimes more slender, and resembling palpi, and sometimes very long; between these plates (which are figured in our first vol. p. 362, col. 2, fig. 1 and 2, as they exist in the bee, under the form of two flattened plates, with a pair of small terminal lobes) arise two other pieces, which are very slender, serrated at the tip in the bees, (fig. 3 and 5), but much broader in the saw-flies, and transversely striated, forming the saws with which these insects are provided; moreover, these two pieces are received, in the bees, into a canal (fig. 2 and 4), but in the saw-flies this gutter is broad, flattened, and divided into two separated parts, forming the backs of the two saws. In the ichneumons, these various parts are so slender, that at first sight they appear to consist but of a single piece; on more minutely examining the instrument, however, it will be found that it consists of a scabbard, composed of two pieces, inclosing a fine hair-like bristle, which is, in fact, the exact analogue of the stinging part of the bee's sting, consisting of three pieces.

These insects, which constitute the fifth Linnæan order, are unquestionably the most interesting of the insect tribes, comprising as they do the bee, wasp, ant, sand-wasp, cuckoo-flies, and saw-flies; the economy of which is so remarkable, that it has attracted the curiosity of the most uninquisitive persons. Their colours are seldom brilliant; brown, yellow, black, or grey, being their prevailing tints; neither do they often acquire a large size, the majority being under an inch in length, and some being so exceedingly minute as to be invisible to the naked eye, except when seen creeping against the light upon a window. Many of the species live in societies more or less numerous, as the bees, ants, and wasps; these assemblages consisting of males and females, and neuters, the latter being abortive females, and destined to perform the more laborious duties of the community. Others, as the sand-wasps, &c., are solitary in their habits, but their economy is not less interesting than that of the former; since, although not exhibiting such a variety of remarkable physiological traits, the construction of a nest, and the provisioning it with a supply of food for the young when hatched, by a single insect, is sufficient to prove that the instincts of that insect are not less developed than in cases where a particular

duty devolves upon a particular set of individuals. We have already, in our articles ANT, BEE, CERCERIDÆ, FORMICIDÆ, HORNET, &c., detailed many of the more prominent features in the economy of those insects, which it will be unnecessary to repeat in this place. From these we find that the food laid up in store by one class of these insects, consists of honey collected from flowers; whilst in another class it consists of insects deposited in cells by the parent fly. Another class have the instinct to deposit their eggs in the already provisioned cells of the working classes, the young of which latter are starved to death by the previous exclusion of the parasitic grub, which devours the supply provided for the former. Another class is parasitic in a different sense of the word, depositing their eggs upon or within the bodies of other insects, chiefly in the larva state, the intestines of which are preyed upon by the grubs when hatched. Others deposit their eggs in the leaves or stems of various plants, together with an irritating matter, which causes the production of galls or warts, often of a large size, upon the substance of which the larvæ, when hatched, continue to feed until they assume the perfect state; and the remainder place their eggs in slits in the stems of plants upon the leaves of which the young feed. From the nature of their food, and their abode in the midst of it, it will be at once evident that they have little need of locomotive organs serving for its discovery. We accordingly find that the majority of the hymenopterous larvæ are footless grubs, of a white colour, and of a fleshy substance, having the parts of the mouth small, and but slightly developed, although in the perfect insect the same organs attain a maximum degree of development. In those larvæ, however, which are external feeders, we find the necessity for locomotion causing the addition of locomotive organs; the legs in the larvæ of the saw-flies varying in number from six to twenty-two. The pupæ of these insects are inactive, having the various limbs of the perfect insect developed, but enclosed in separate cases, and lying along the breast. In this respect, therefore, they resemble the coleoptera, and like them they are in this state either enclosed in cocoons formed by the grubs previous to their transformation, or are naked. The species of this order is extremely numerous. They are annual insects; the majority of them pass the winter season in the form of grubs or pupæ, whilst others pass this period in the perfect state. These, however, are but few in number, and consist of females which have been impregnated during the preceding autumn, and are destined to become the foundresses of fresh colonies, upon the arrival of spring. In their perfect state, they feed almost exclusively upon the honey of flowers. Some, indeed, have been said to feed upon other insects, but these observations have been made upon a casual occurrence, or upon insects which were in the act of securing the supply of food for their progeny. In the tropical countries, the species attain the largest size; there, too, they appear to be the most abundant.

The situation of this order in the classification of insects, is especially interesting. The possession of a pair of robust mandibles necessarily places it amongst the mandibulata or masticating insects, whilst the elongated structure of the lower parts of the mouth, forming a proboscis for sucking up the honey of flowers, seems to unite it with the haustellated or sucking insects. Latreille has accordingly placed it between the mandibulated *Neuroptera* and

the suctorial *Lepidoptera*. This order has been considered a very natural one by all entomologists. Our great author, Ray, was the first who had any idea of the group, which was named by him *Tetraptera* or *Quadrupennia*; but he included therein the *Phryganidae* and *Ephemeridae*. It was not, however, until the tenth edition of the *Systema Naturæ*, that the order was reduced to its present limits. In the twelfth edition of the same work, three hundred and fourteen species were described, but the number is now vastly increased. The increase in the number of genera has kept pace with that of the species, so that, had it not been for the philosophical institution of family groups, by Latreille, corresponding in many instances with the Linnean genera, this and the other orders of insects would have become a perfect chaos. The structure of the parts of the mouth, as appearing to indicate the essential habits, might be regarded as of primary importance in determining the classification of the insects; but it is essential to bear in mind the following circumstances, which may have the effect of proving that too great a weight ought not to be allowed to these considerations. We have already said that the *Hymenoptera* in general feed upon the honey of flowers—hence, unlike the *Coleoptera* (in which some are predaceous, others lignivorous, others herbivorous, and others necrophagous) an uniformity in the mode of nourishment exists; the only variation consisting in the employment of the sap exuding from the wounds of plants, or the juices of fruits. If, indeed, certain of the *Tenthredinidae* (such as *Tenthredo scrophulariæ*) attack other insects, they form but an exception to a general rule, which they and some other species infringe but rarely, and, as it would seem, only when the excessive heat has dried up the supply of honey. The ants and wasps also appear to offer exceptions to the rule, but it is not real, since as they are often found upon flowers, of which they will suck up the honey, it is presumable that this is their ordinary food, and that if they destroy other insects, it is only for the purpose of getting at the honey with which the latter are gorged. Moreover, in the nests of certain social wasps, and even in that of the *Polistes Licheguana* of Brazil, as observed by M. Auguste de St. Hilaire, a quantity of cells, full of honey, have been found, of which this distinguished traveller ate a considerable quantity without experiencing any inconvenience; and the same has been observed in respect to the honey found in the nests of *Polistes gallica*. The larger species of wasps will occasionally attack raw meat in butchers' shops; but this is of rare occurrence, and can be only attributed to an occasional diminution of their ordinary food; indeed many nests are too far distant from the habitations of man, for the wasps which inhabit them to have recourse to such a kind of food. In the same manner may be explained the interesting instance of supposed instinct exhibited by a wasp, recorded in some of the popular works on natural history, which had captured a fly which it was unable to fly away with, owing to the wind acting upon the wings of the latter, whereupon it clipped off these wings and also the legs, and then flew off with it to devour it at leisure. Here it was evident that the wasp had been prevented from obtaining its usual supply of food, and that its instinct had been sharpened by hunger. We were witness some time ago of another equally interesting instance of instinct exhibited by the same insect, which had discovered some flies upon which it wished to make a

meal, revelling upon excrement, which it was anxious not to touch with its feet or wings in seizing its prey. It approached, therefore, as near to one of the flies as it could, and then with a swoop, which reminded us of the flight of the hawk, darted upon the fly, and carried it off without soiling itself. The ants, in like manner, although some of them have the instinct to secure in their nests entire colonies of aphides, do not devour them, but merely lap up with their tongues the saccharine fluid which they emit, and which is, in fact, merely vegetable liquid slightly modified during its passage through the body of the aphid. All other species of hymenopterous insects observed killing, wounding, or dragging along other insects, caterpillars, or spiders, have been ascertained to be employed, not in providing for their own support, but for that of their offspring. The elongation of the parts of the mouth of the *Coleoptera*, has been regarded as a character indicating carnivorous appetites; and hence the same idea has been applied to those hymenoptera which have the trophi, especially the jaws, elongated; but observation has proved that these species are destined to carry heavier burdens than the others; their prey destined for their progeny is more weighty, and they consequently need more powerful tools for its transport. Now the *Coleoptera* have no work of this kind to perform, and consequently the analogy cannot be supported: and this observation, as it appears to us, offers an interesting clue to the solution of the oft-debated question, why it should be requisite to employ characters derived from so many distinct organs in the natural classification of any extensive group of animals, instead of deriving them throughout the group from a single organ.

In one order of insects, for instance, we find the primary divisions founded upon variations in the construction of the tarsi, whilst in other orders the structure of these parts is uniform. Thus it is only by acquiring a perfect knowledge, not only of the structure, but of the habits of animals, that we can ever hope to be made acquainted with the relative value of this or that character, so as to be able to affirm, with any thing like precision, that the one or the other is of the greater importance; and this happens to be a question of considerable moment in respect to the order at present under consideration, in which some authors have distributed the families according to their general structure, whilst others, and more especially the Count de St. Fargeau, in the work above mentioned, have regarded the various instincts of the insects, as exhibited in their social, solitary, or parasitic qualities, as of the highest value, although these qualities may have but a very slight influence upon the general structure of the insect; thus between the humble bee and the parasitic humble bee (*Psiithyrus*), there is so little general variation of structure, that Mr. Curtis even doubts the propriety of their generic separation, whilst St. Fargeau, looking at their different instincts, places them in totally distinct sections, regarding the slight modification of form in the legs, (dependent, it is true, upon the polliniferous or parasitic habits of the different insects), of far higher importance than that entire variation of structure which separates such families as the working bees and wasps, which are united together by the common tie of sociality. As regards the order of insects in question, this mode of viewing their classification has hitherto been too much neglected to enable us to follow it out in a work like the present, which ought to

convey facts rather than theories; we have nevertheless thought it proper to notice the subject, which is in fact one which materially influences every zoological group. In the meantime it may be more conducive to our present purpose to notice the variation of several of the more important organs, and the causes upon which such variations are dependant. Although the nature of the nourishment of all hymenopterous insects be alike, it does not follow that the mouth of all should be of an uniform structure; neither, although consisting of the same parts and number of pieces, is it requisite that they should be formed upon the same model. The construction of the nest and the preparation and transporting of the materials employed therein, as well as the form of the flowers from which the different species collect their honey, are considerations which modify, in a greater or less degree, the structure of the organs of the mouth; thus in those species which collect honey from flowers for their own support alone, as the *Tenthredinidæ*, *Ichneumonidæ*, &c., the lower lip or tongue and the lower jaws are short and narrow, but when the insect has to collect a supply of food not only for its own support, but also for that of its progeny, these parts are much more developed, as is also the case when the honey is placed at the bottom of tubular flowers, such as the *Labiata*, &c., which are much frequented by some of the long-tongued bees; the same parts are short and broad in the ants, wasps, &c., because they frequent flowers composing the heads of the *Umbellifera*, from the almost flat surface of which they collect the honey, as well as the sap flowing from the wounds of trees, &c., without trouble; moreover, this organ is thus modified to serve as a trowel for the smoothening of the inner surface of the cells in which the future progeny are to be produced. Again, in those species which have to search with much diligence for the prey destined for the nourishment of their progeny, the palpi (which appear to be organs of touch) are elongated; whereas in those whose larvæ are nourished with honey, they are short, the flowers being discoverable without difficulty by the sight or by the antennæ. Again, the mandibles vary in their form, size, thickness, and toothing; thus, in the females of some genera, they are more robust than in the males, the former sex being the sole architect of the nest, and having to perform more laborious work than her partner; so in those females which have to cut the materials for their nests, they are thicker, whilst in those which have heavy burdens to carry, they are longer; but the most extraordinary instance of this kind of variation in the last named organs occurs in the neuters of some species of ants. Many observers have remarked in the same nest neuters with large and others with small jaws, the former being employed in collecting food, and the latter remaining in the nest, out of which they only make their appearance to attack any enemy that may menace their community. M. Carcel was witness of this fact (first observed by the celebrated Huber), the former of whom was witness of the destruction of a scorpion by these minute but extraordinarily developed workers. M. Le Prieur has also observed that the nests of the South American visiting ants (*Atta*, Latreille), the neuters of which have short jaws, are defended by other workers with exceedingly long mandibles; which organs are employed in stopping those individuals which quit the ranks and might thus be lost, showing them the right way. Latreille, not being aware of this remarkable

fact, has formed these long-jawed individuals into a distinct genus under the name of *Eciton*.

Many other equally interesting instances might be given of the variations and causes of variations to which not only these but other essential organs, as the ovipositor, legs, &c., are subject; but we have advanced sufficient to prove that this branch of the subject, which may without hesitation be laid before the reader almost as an unopened field of inquiry possesses a very great degree of interest, sufficient to repay the labour devoted to its elucidation.

The following is the classification of this order, given to us by Latreille, to whom indeed we are greatly indebted for our knowledge of these insects, which were especial favourites with this celebrated author.

Section I. *TEREBRANTIA*; abdomen of the females furnished with a saw or borer.

Sub-sec. 1. *Securifera*; abdomen sessile furnished with a saw; larvæ with feet. Families, *Tenthredinidæ* (saw-flies), *Siricidæ*.

Sub-sec. 2. *Pupivora*; abdomen pedunculated, furnished with a borer; larvæ without feet. Families, *Evanidæ*, *Ichneumonidæ*, *Cynipidæ*, *Chalcididæ*, *Proctotrupidæ*, *Chrysididæ*.

Section II. *ACULEATA*; abdomen of the females (and neuters) armed with a sting.

Sub-sec. 1. *Heterogyna*; females or neuters wingless. Families, *Formicidæ* (social), *Mutillidæ* (solitary).

Sub-sec. 2. *Fossoræ*; females winged, wings not folded, basal joint of posterior tarsi simple. Families, *Scoliidæ*, *Sapygidæ*, *Sphegidæ*, *Bembecidæ*, *Larridæ*, *Nyssionidæ*, *Crabronidæ*.

Sub-sec. 3. *Diptoptera*; females (and neuters) winged, wings folded. Families, *Masariidæ*, *Vespidæ*.

Sub-sec. 4. *Mellifera*; females (and neuters) winged, wings not folded, posterior tarsi with the basal joint large and compressed into a polliniferous organ. Families, *Andrenidæ*, *Apidæ*, with its subdivisions, for which see our article *APIDÆ*.

**HYOSCYMUS** (Linnæus). A genus of annual and perennial herbs, natives of Europe. One of them, the *H. niger*, is the well-known henbane of British wastes. These plants belong to their natural order *Solanææ*. The henbane is a powerful narcotic, and, when taken in any considerable quantity, proves quickly poisonous to man, and most brute animals except swine.

**HYPERECINEÆ**. A natural order of plants, of which *Hypericum* is the type. It contains seven genera, and above ninety species. The whole abound in a resinous juice. Their leaves are all dotted, and, what is very remarkable, the dots are often black, even upon the yellow petals. They are herbs, undershrubs, or trees; the stems are jointed, and the intermediate joints are round or tetragonal; the leaves opposite simple, entire, very seldom alternate or crenate, and either sessile or short-stalked. The inflorescence is mostly in terminal cymes; the flowers are regular, united, and in general yellow; the fruit is capsular, or baccate, many-valved and many-celled. The plants of this order are found in the more temperate parts of Europe and Asia, and often in the shady parts of woods. The genus from which the order receives its title is the *Hypericum*, or St. John's Wort of English authors, seven or eight species of which are natives of this kingdom.

**HYPOXIDÆ.** A natural order of exotic plants, containing three genera and about twenty species. *Hypoxis*, the genus whence the order is named, was formerly associated with the *Asphodeleæ*, till separated therefrom by Dr. Brown. It seems to be a link of connexion between them and the *Amaryllidææ*, from which last it but slightly differs. The foliage of these plants is plaited, harsh, and rigid, which circumstances seem to argue them distinct from both *Amaryllidææ* and *Asphodeleæ*. *Hypoxis*, *Curculigo*, and their few allies at present known, are plants of little beauty, *H. stellata* excepted. Their uses are unknown.

**HYRAX** (*Hyrax*). A genus of pachydermatous mammalia, intermediate in their character between the rhinoceros and the tapir; but so inferior to them in the size of the existing species, that it was not until Cuvier had demonstrated the character of the animal from its anatomical structure, that it was admitted into this part of the system; and it was previously classed by naturalists with the rodentia or gnawing animals. No part of the structure allows it, however, to be ranked with them, while every thing justifies the place assigned to it by Cuvier. The general appearance is that of a rhinoceros in miniature; and though it has no horny production on the nose, it has the same character of the grinders, and the same prehensile upper lip. The incisive teeth are different, for there are in the upper jaw two large incisors bent backwards, with a wide space between them and the cheek teeth. The foremost cheek teeth above have flat triangular crowns, and the posterior ones are a little hollowed: the under ones have transverse ridges on their crowns. In the full grown animal, there are no canines; but in the young state, there are small ones, which soon drop out, and are never replaced. The incisors in the lower jaw are four in number, and much smaller than those in the other; but they are, properly speaking, tearing teeth, and not cutting ones, though from the character of the cheek teeth, they are made for tearing vegetable matter only; the fore feet are furnished with four toes in one of the known species, and only three in the other, while the hind feet have four toes in both; the claws upon these toes are, properly speaking, little hoofs, which are the characteristic armature of the pachydermata, but the inner toe of the hind foot is furnished with a crooked claw; the nostrils are oblique; the eyes small; the ears short, but of considerable size; the head large for the size of the body; the upper lip divided; six mammae in the females, two on the breast, and four on the belly; and the body covered with two descriptions of hair, one short and woolly, and the other long and silky; internally, the stomach is divided into two portions; there is a large cæcum, and various enlargements in the colon. All these characters are strictly those of the pachydermatous animals, and leave no doubt as to the correctness of the modern arrangement.

It is not a little remarkable that we should find the remains of those smaller animals of this order in the places where the largest ones are also found; and it is especially curious that we should find both species of this genus in Africa, on opposite sides of the equator, and nearly under the same meridian. This would lead us to conclude that at some early period of its history, the character of a large, and probably the principal part of the African mammalia, was pachydermatous; but that in the progress of the country toward dryness, those heavy and comparatively slow-

going animals, have given place to those ruminants, which are found in such multitudes upon the African plains. We have not space, however, for entering upon this speculation, and all that we can do is to refer it to the attention of the reader. We shall, therefore, now only notice the two species.

**CAPE HYRAX** (*H. Capensis*). This one has four toes on each of the feet; is of a greyish brown on the upper part, and whitish on the under, and also the insides of the ears. It has been called a marmot by naturalists; and the colonists of Southern Africa have termed it the rock-badger. It is about two feet six inches in length, from the muzzle to the extremity of the body; it has no tail, except a mere tubercle; and it stands about eight inches high on the legs. It lives in the clefts of the rocks, where it contrives to secure itself tolerably well from beasts of prey. The woolly hair upon it is fine and soft; and the silken hair is pretty long and of irregular length, so that some hairs of it project much farther than others. The soles of the feet are covered only with a thick soft skin. It is a docile animal; not very difficult to tame; playful when in a domesticated state, and capable of a considerable degree of attachment.

**SYRIAN HYRAX** (*H. Syriacus*). The chief difference between this species and that found in Southern Africa consists in its having only three toes on each of the fore feet, while the other has four. It is found as far to the southward as Abyssinia; and is the *ash-koko* of that country described in Bruce's Travels, the fidelity of which in natural history, as well as in all other matters, has been so fully established by the testimony of more recent travellers. It has sometimes been alleged that there are other and smaller species of this genus; but it does not appear that the allegations are entitled to credit. The hyrax possesses twenty-one pairs of ribs; the elephant and tapir twenty; the rhinoceros nineteen; and the solid-hoofed animals eighteen.

**HYRIA** (Lamarck; *Mya*, Gmelin). Lamarck separated this genus from those of *Mya*, *Unio*, and *Anodon*, with which they had previously been blended. These molluscs differ from the *Unio* not only in general shape, but in the form of the cardinal tooth, particularly that of the right valve. They much resemble the *Avicula* in appearance, and probably inhabit lakes rather than rivers. The substance of the shell is solid and beautifully pearly; it is equivalve, obliquely triangular, auriculated, and the base truncated and straight; the hinge with two projecting teeth, one of them posterior or cardinal, divided into numerous divergent parts, the anterior ones smaller, and the others anterior or lateral, being very long and lamellar; the ligament is linear and external. They possess a strong epidermis, and the animal entirely resembles the *Anodon* in its organisation. Strictly assuming Lamarck's definition of this genus, but two or three species would be known; but more recent authors on malacology have determined upon making the hyria no other than a sub-division of the genus *Unio*, in which also another of Lamarck's genera, *Castalia*, is now considered only a sub-division; and we feel disposed to place Dr. Leach's *Dipsacæ* in the same situation. Considering, therefore, the family *Unio*, their number is immense, and daily increasing by the extended researches of naturalists. The genus *Hyria*, as above defined, inhabit America, and many new species may be discovered in other parts of the warmer climates of the south.

**IANTHINA** (Lamarek; *HELIX*, Linnæus).—This singular shell was confounded by Linnæus with the genus *Helix*, the impropriety of which may at once be pointed out by stating that the *Ianthina* is a marine, and all the *Helices* are terrestrial molluscs—in general form, also, it varies from the *Helix* in many respects when examined with any thing beyond a cursory glance. The shell is extremely fragile—thin, transparent, and imbued throughout its substance with a beautiful violet colour. The form is round and ventricose, the whorls slightly angular, spire obtuse, columella straight and continued below the base of the right side, occasioning an angle to be formed at the lower part of the aperture; a sinus or notch exists in the margin of the lip, but it is seldom met with in a perfect state from the extreme delicacy of the shell; and some authors are of opinion that it only occurs in the female species. These shells are found floating on the surface of the sea, suspended by a bladder-like appendage attached to the animal's foot, and closing the aperture of the shell in the manner of an operculum; from this a violet liquor is emitted when the animal is touched or injured, whence the name of the genus is derived. Many naturalists were of opinion that this vesicular appendage contained the eggs of a future generation; but this appears unlikely, as every species is furnished with it; and if the assertions of the late Sir Everard Home are to be credited, he has seen the eggs of this mollusc dispersed on the exterior of the shell, and thus carried to a certain period of their development, which he adduces as one of the few instances known, of any thing like a superior instinct being exhibited by molluscous animals in the care of their progeny. The facts cannot, however, long remain doubtful, as one species is not very rare in our seas, though the other inhabits the warmer latitudes. Supposing the notch in the lip of the shell to constitute a distinction of sex, no subdivision of the genus would be necessary; and as there are but three or four species known, that question cannot, as yet, be conclusively answered till further observation shall have determined the position of the eggs, and proved, as appears most likely, that the bladder-formed appendage to the animal's foot is merely a wise and necessary provision of nature to assist locomotion, since without it the specific gravity of the shell would be greater than the medium through which it is seen to travel or become suspended. Some of the aquatic insects are beautifully provided with the faculty of expelling small air-bladders to their covering, by which their rise to the surface of the water is facilitated, or altogether accomplished; and the absence of such a provision as that we speak of in the animal—found in the *Argonauta*, has been often urged in evidence of its being a pirate, and not the "architect of its fairy boat." That the wisdom of the Almighty Creator of all things is manifested as much in the smallest work of nature as in her stupendous productions, all rational beings will confess—but to fathom the full extent of that wisdom, is not allotted to man; all he can do is by patient investigation and continued reasoning to assign some probable effect to certain natural indications, and this leads him to the beautiful results of a knowledge of comparative anatomy, and a greater reverence towards Him, who said, Let it be, and it was.

**IBERIS** (Linnæus). A genus of annual and biennial herbs, and perennial under shrubs, mostly natives of the south of Europe. They belong to *Cruciferae*,

and are well known by the name of candy-tuft, so frequent in every flower border. *I. odorata* is fragrant as well as pretty, and the whole genus is remarkable for the cruciform corolla becoming irregular, the two outer petals of the external flowers in its dense corymbose panicles being longer than their fellows, and even ligulate.

**IBIS**. A genus of *Echassiers*, or stilt birds, belonging to the family of birds with long bills, and resembling the curlews more than any other genus. They are of larger size, however, and, generally speaking, inhabit warmer countries, where they frequent the margins of the larger rivers. The true ibis appears to be confined to the eastern continent, though the American genus, *Tantalus*, which agrees with it in many habits, and answers the same purposes in that quarter of the world, as the ibis does in the east, has sometimes been confounded with it. The characters of the genus are: the bill long, slender, arched, enlarged at the base, and depressed at the tip, which is rounded and obtuse; the upper mandible furrowed with deep nasal groves for its whole length; the nostrils placed in the base of the upper mandible, and partially covered by a membrane which also lines the nasal groove; the front, and often part of the head covered with naked skin; the feet very slender, and having a naked garter above the tarsal joint; four toes on the feet, of which the middle and upper ones have pretty large webs, and the middle and inner shorter ones, and the hind toe sufficiently long for touching the ground. Some species, however, have the tarsi short and with reticulated scales, and these have the tarsi and also the bill comparatively stout. The others have the tarsi shielded with plates, and their bills are in general smaller.

**SACRED IBIS** (*I. religiosa*). This bird has been very celebrated from comparatively remote antiquity, for its real or supposed services to the ancient Egyptians, in destroying offensive and poisonous reptiles, and generally for scavengers' work done about the temples and houses. For these reasons it was admitted into the temples themselves among the numerous other animal gods of the Egyptians; and mummies of it were preserved with the same assiduous labour of embalming as those of men and monkeys. Notwithstanding this ancient celebrity, however, and the pains which were taken to perpetuate specimens of the carcass of this animal, those schemes did not accomplish their purpose; and in times comparatively modern, there have not only been disputes about which species is the sacred ibis; but some have contrived to mystify the matter to such an extent, that, if we did not possess the living bird to which we can appeal for its own history, we should have remained ignorant as to what bird received those high honours in the olden time.

Bruce was the first who, in modern times, gave an accurate account of the bird; but it was not until other evidence had been produced in corroboration of his statements, that he received the credit to which he is so well entitled. This bird is not confined to Egypt, but is very generally distributed throughout Africa. It is a bird about the size of a common fowl, with the plumage entirely white, except the quills, the points of which are black, and the last coverts of the wings have long and slender barbs also of a black colour, and with violet reflections, which hang down over the extremities of the closed wings and the tail;

the bill and feet are also black, and so is the naked skin on the head and neck. These birds are very common in the central parts of Africa, and also in that part of the valley of the Nile which is liable to be flooded. Sometimes they are found solitary, and at other times they are found in groups, but seldom more than ten or twelve are in close society with each other. A number of these little groups are, however, often found close to each other, especially after the water of the Nile has begun to subside, and the banks are for some extent covered with soft mud. This mud they search with the most patient industry with their bills; and in moving about while on the ground they do not hop and run nimbly as the curlews do, but march along with measured steps; when on the wing they project the head forwards and the feet backwards; but there is not the same majesty in their aerial journeys as there is in those of the storks and cranes, neither do they extend their migration so far to the northward. Their flight is powerful, however, and they rise to a great elevation.

It does not appear that there is a very great deal of foundation for that clearing of the country of poisonous reptiles, on account of which the Egyptians are said to have held the ibis in such veneration; for the chief ground adduced for this propensity in the old account given by Herodotus, is the antipathy which the ibis had to the serpent race. In consequence of this the bird is said to have acted the part of a sort of preventive service, to hinder the serpents from smuggling themselves into the Egyptian territory. Now this is so contrary to the whole tenor of animal conduct, that it can hardly, in the nature of things, be true. Animals do not kill each other from what we call antipathy, unless in the case of those males which fight battles of gallantry for their females—we believe the propensity goes no farther; and the greater number of them, whether mammalia or birds, are vegetable feeders, and never kill other animals for the sake of eating. On the other hand, we believe there is no animal which kills, or even offers to injure, any other species, except for the purpose of feeding on that species; and, therefore, if the ibis have been a serpent-feeder, it must have eaten the reptiles from liking them, and not from antipathy to them. Besides, there are not in those places of the country to which chiefly the ibis resorts, very many serpents for the birds to eat, either from liking or disliking. Water serpents are not, we believe, very numerous in the Nile; and the land serpents of Egypt are chiefly, if not exclusively, found in the dry and sandy places in which the ibis seldom if ever seeks its food; besides, the bill of the ibis is not of a very serpent-killing character; for though it is stouter and harder than the bills of the true snipes, and even than that of the curlews, it is still a bill of the same class. Birds with the more characteristic bill of this form feed chiefly upon small mollusca, and other little animals which they find on the moist surface of the ground, or in the sludge; and so far as has been observed in modern times, the ibis seeks its food in similar places, and hence we may conclude, that it feeds on substances of a similar kind. Birds which do feed on serpents are always very long in the tarsi, which is not the case with the ibis, and they also have powerful bills. Cultrirostral birds, such as cranes and storks, and the other birds of that family, are more likely to perform this office than such a bird as the ibis. It

may be true, however, that the America species of *tantalus*, which is a hard-billed bird, and does eat reptiles, may have been confounded with the ibis in ancient times, as it has sometimes been by modern naturalists.

**GLOSSY IBIS (*I. falcinella*).** This is a much more discursive bird than the preceding species; and though it ranges over the tropical countries, and appears to have its head-quarters there, yet it makes excursions over a considerable part of Europe. The characters are: the head, the neck, the front of the body, and the sides of the back, of a beautiful chestnut colour; the upper part of the back, the wings, and the tail, are of a bronze or golden-green, as the different shades of light reflect upon them. The bill is greenish black, and the tip brown; the irides are also green, and the legs are greenish brown. It is about twenty-three inches in length. The young have the head, throat, and neck feathers striped with blackish brown before they reach their third year. These feathers by this time are also margined with white. The breast, the belly, the thighs, and the under part of the neck are of a black ash colour, the upper part of the back and scapularies brownish ash, and the golden green reflections of the wings are of a duller hue than in the adult birds. It haunts the margins of the lakes and rivers, and visits, in passing, Poland, Hungary, Turkey, and the Archipelago. It is also met with on the banks of the Danube, and frequently in Switzerland and Italy, and occasionally, though more rarely, in Holland and the British islands. It is not uncommon in Egypt, where it appears as a regular visitant at that season when water birds resort in such numbers to reap their portion of the harvest of the Nile. As a European bird, however, it belongs much more to the eastern migration between the valley of the Danube and the rivers of central Asia, than to the southern migration. Its breeding places are not correctly known; but they are understood to be chiefly in Asia. The food consists of insects, worms, fresh-water mollusca, and occasionally vegetable substances; and from the generic resemblance that there is between them, there is every reason to believe that the food of the Egyptian species is the same. The young of this species have sometimes been described as a different one, under the name of the green ibis. Indeed the names ibis and *tantalus* have been so habitually given to the same birds, that there is a great deal of uncertainty about both genera. There is no doubt, however, that Cuvier is correct in ranging *tantalus* among the birds which have knife-shaped or trenchant bills, which are capable of mastering animals of considerable power; and ibis among those which have long bills fitted for dabbling. In the present genus the bill is not so completely covered with sentient membrane as in some of the others; but still there is no doubt that the lining of the nasal grooves is an organ of sense. We shall have occasion to revert to the place of these birds in the system when we come to the article *TANTALUS*.

**ICE PLANT** is the *Mesembryanthemum crystallinum* of Linnæus, a curious annual, very frequently seen in our green-houses. The plant belongs to the natural order *Ficoideæ*.

**ICHNEUMON (*Mangusta*).** A genus of carnivorous mammalia belonging to the family of *Viverridæ*. The characters are: six incisors, two canines, and twelve grinders in each jaw. Three of those in

the upper are false grinders; and there is one large carnivorous tooth, and two tuberculated ones. In the lower jaw there are four false grinders, one large carnivorous tooth, and one large tuberculated one. The head is long; the muzzle pointed, the pupils of the eye contract to a line; the tongue is rough; there are five toes on each foot, and the animals are furnished with an anal pouch of considerable size. There are several species, all natives of Africa and south-eastern Asia. They are animals of small size, of prowling dispositions, but not remarkable for ferocity. Figures of the two best known species are given in the plate *ICHNEUMON*, and we shall first very briefly notice them.

**EGYPTIAN ICHNEUMON** (*M. Ichneumon*). This species inhabits the banks of the Nile; and it has been scarcely less celebrated than the ibis itself. It is too weak and too timid for being able to attack adult crocodiles, serpents, and the larger lizards; but it is by feeding on their eggs and destroying the young that the ichneumon decreases the number of these obnoxious creatures. It is not an animal of a decidedly carnivorous appetite, though it occasionally lives on animal food. When urged by its natural instinct of destruction, it is often met with after night-fall cautiously prowling along the rough surface of the soil in search of its prey, and at the same time cunningly avoiding all appearances of danger. When it is fortunate enough to succeed in these researches, it does not stop with the gratification of its appetite, but goes on destroying every animate creature it can safely attack. It is particularly fond of eggs, which it seeks after with great assiduity, and the gratification of its palate in this way causes the destruction of a great many crocodiles. It is a mere fable that it enters the mouth of the crocodile when asleep; but such fables are very common in all countries in the age of superstition.

These animals possess a considerable degree of sagacity, and have a strong disposition to explore and scrutinise places which are new to them. The sense of smell appears to be of great use in guiding them to their prey: but their other senses are not so acute. It waits and watches with great patience, and also shows much perseverance in search of prey. On these accounts, and from its comparatively gentle disposition, it is pretty generally kept in a state of domestication, in which it answers nearly the same purpose as the domestic cat. In this state they readily know the houses of their keepers, and those persons who feed or otherwise kindly use them, though they do not show any sign of the watchfulness and attachment of the dog. They are, however, not insensible to caresses; and though they are apt to be sulky if disturbed when feeding, they never attempt to regain the wild state after they have been once domesticated.

**THE INDIAN ICHNEUMON** (*M. Mungos*). A figure of this species is given in the same plate with the former, from which some general notion of the aspect of the animal may be formed. It is of a dull grey colour, arising from the marking of the hairs, which is an alternation of rings of black and white. The tail is of the same colour as the body, very thick at the basal part, but tapering to the extremity, a small portion of which is yellow. It is smaller than the African species, being little more than a foot in length, and five inches high in the most elevated part of the back; but the tail is very long, nearly equal to

the whole length of the body. It is very common in many parts of India, and so far from shunning the habitations of men, it often takes up its abode in holes of the walls of houses, or in small burrows in the ground, which it digs with great readiness. It is easily tamed, and when fed it is playful; but the sight of those animals which form its natural prey excites it so much that it is apt to bite, if not released so as to be suffered to pursue them. It partakes a little in the habits of the cat; and one might expect as much from all the species, inasmuch as they have the claws semi-retractile, and use them partially in capturing their prey. It is exceedingly fond of birds, and very dexterous in seizing them. It jumps upon them like a cat, with far more rapidly than one would expect from the general appearance of the animal.

There are several other species, or at least varieties, found in the eastern peninsula of Asia, and in Java and the other islands situated around the extremity of that peninsula. The chief difference among these is difference of colour, which renders it not improbable that they are all originally of the same stock. The one which inhabits Java is found most abundantly in the forests of large trees. It is an active and energetic animal, not indisposed to associate with man, but rather destructive of eggs and young birds in the poultry-yard. From the accounts that are given of it, it appears to be more sensitive to kindness than the other species; for it follows its master like a dog, stands up on its hind legs to be played with and caressed, and shows other evidences of being pleased with attention. Some of the animals which probably ought to belong to this group are placed in other genera; so that we shall notice the remainder of them, and also the general relations of the family, in the article *VIVERRIDÆ*.

**ICHNEUMONIDÆ** (Latreille). A very extensive tribe or family of *Hymenopterous* insects belonging to the section *Terebrantia*, or those destitute of a poisonous sting, and subsection *Pupivora*, Latreille, or those which are parasitic upon other insects. In this family the wings are furnished with various veins, the anterior pair having several complete and closed cells. The abdomen, which is narrowed at the base, is inserted between the posterior pair of legs; the antennæ are long and filiform, or setaceous, composed, for the most part, of a very great number of short, cylindrical joints. They are constantly kept in a state of vibration. In the majority the jaws are not furnished with a strong internal tooth, and they are generally slit at the tips. The maxillary palpi do not generally consist of more than five joints, which are long and slender; the ovipositor, which, as we shall subsequently see, is an organ of the greatest importance in the economy of these insects, is composed of two external filaments enclosing a slender cylindric instrument which, although apparently consisting of a single piece, is, in reality, formed of a sheath inclosing two very delicate and serrated threads.

These insects were named by the old authors *Musca tripiles*, from the three setæ which compose the ovipositor, or *Musca vibrantes*, from the constant vibration of the antennæ, which are often curled at the tips with a band of white or yellow towards the middle; the body is generally long, slender, and narrow; the ovipositor sometimes being protruded to a very great length, far exceeding that of the entire body, and sometimes being so short that it is not externally visible, in which case the body is pointed at

Indian Ichneumon

Egyptian Ichneumon.

the tip; in the former case the abdomen is thickened at the extremity, and obliquely truncated. The central piece of the ovipositor is the only part which is employed in introducing the eggs of the insect into the bodies of those insects which are selected by the females for their reception; it is more horny than the external sheaths, and of a brighter colour. Although this instrument is very analogous in its construction to the sting of the bee, it cannot in strictness be regarded as such an organ, although the ichneumon, when held in the fingers, endeavours to employ it in a similar manner by attempting to prick the hand; no ill effect, however, is to be apprehended from the workings of the instrument: in those species, however, which have the ovipositor short, the organ is certainly capable of piercing the skin in tender parts, and of causing a slight pain, arising, probably, rather from the wound than from any deleterious fluid introduced at the time. These insects were comprised with some other parasitic groups, as the *Chalcididæ* and *Proctotrupidæ*, in the Linnæan genus *Ichneumon*, a name given to these insects by the ancients, from the services which they performed to agriculturists by the destruction of vast numbers of caterpillars, in the same manner as the quadruped named *Ichneumon* was supposed to destroy the posterity of the crocodile by the Egyptians, who considered that the former animal not only demolished the eggs of the latter, but even killed the crocodile by introducing itself into its body, and devouring its entrails: the analogy does not, however, entirely hold good, since the *Ichneumon* fly merely deposits her eggs within the body of the caterpillar, the grubs hatched from which devour its entrails by degrees.

We are indebted to Mr. Marsham for an account of the proceedings of one of the largest British species, *Pimpla manifestator*, which is provided with a very long ovipositor, published in the third volume of the Linnæan Transactions, and which it may be serviceable to detail as giving a general notion of the habits of the family. This species was observed by him on the top of a post in Kensington Gardens, moving rapidly along with its antennæ bent in the form of an arch, and kept in a strong vibratory motion, and which the *Pimpla* introduced into a hole made by some insect. In this situation it remained for a minute, and then withdrew them, and going to the opposite side it again repeated this proceeding, which was a third time repeated at the side of the hole. Having again drawn out its antennæ, it turned about, and dexterously measuring a proper distance, threw back its abdomen over its head and thorax, lowering the long and slender ovipositor which it introduced into the hole, remaining in this situation two minutes; it then withdrew its ovipositor, turned round, and again applied its antennæ to the hole as before, and again inserted its ovipositor, repeating the operation three times. On another occasion, Mr. Marsham observed several of these insects at work, but these appeared to pierce the solid wood with the central part of their ovipositors, which they succeeded in doing to half their entire length, constantly supporting them in a straight position with their posterior thighs. It appeared truly surprising to see an instrument, apparently so weak and slender, able, with the strength of so small an animal, to pierce solid wood half or three quarters of an inch deep; but it was perceived that the operation took place through the centre of a small white spot, resembling

mould or mildew, which, on minute examination, was found to be fine white sand, delicately closing up a hole made by the wild bee, *Chelostoma maxillosa*, for the reception of her cells, and which, no doubt, contained the larva of that insect. The writer hereof has, however, often watched these and other species of the family boring into palings, without being able to perceive the slightest trace of any operations performed by other insects, although it is not to be questioned that the larvæ of some insect or other were ascertained by the *Ichneumons* to be in such spots, at a depth in the solid wood. In deep holes which were not closed, the *Pimpla* not only thrust in the entire ovipositor, but in some cases the whole of the abdomen and posterior legs, leaving out only the two fore legs and the wings, which it spread out in opposite directions, like arms. At such times the external cases of the ovipositor were also projected over the back, with the ends appearing above the head out of the hole. The *Pimpla*, indeed, does not adopt indiscriminately any hole for the reception of her eggs, since Mr. Marsham observed that in many instances he saw it thrust the antennæ into holes and crevices from which it almost immediately withdrew them, and proceeded in search of others; it is, therefore, only in such holes that are inhabited by the insects which are the genuine receptacles of the eggs of the parasite, that the *Pimpla* selects for the deposition of her eggs; and that this information is obtained through the medium of the antennæ, appears certain, but in what manner, and whether by the sense of smelling, or hearing, or feeling, we can by no means decide.

*Pimpla manifestator* engaged in oviposition.

In the insect whose proceedings we have thus detailed, we have seen that in consequence of the deep retreats in which the young of the bees are lodged, it is necessary that the *Ichneumons*, which are destined to keep them in check, should be provided with an ovipositor sufficiently long to reach them in their cells; but other species which have no difficulties of this kind to contend against, are provided with a very short ovipositor, whereby they are enabled to penetrate the soft and naked bodies of caterpillars. We have already in our account of the family, or more properly sub-family, *Braconides*, given an account of the proceedings of some of the *Ichneumons*, which are parasitic upon the plant lice. Mr. Kirby has recorded an account of one of the species which is eminently serviceable in keeping in check the little midge (*Cecidomyia*), which attacks the wheat when in flower.

Having placed a number of the grubs of this mischievous insect upon paper, he introduced a female *Ichneumon* amongst them : she immediately began to pace about, vibrating her antennæ very briskly, whereby she soon discovered one of the larvæ, upon which she immediately fixed herself; her antennæ vibrating very intensely; then bending her abdomen beneath her breast, she inserted her ovipositor, and whilst the egg was depositing, the antennæ became perfectly motionless. The larvæ when pricked gave a violent wriggle; this operation was repeated with all which had not already received an egg, for only one is committed to each larva. Mr. Kirby noticed that when it mounted one which had already received an egg, it soon discovered its error, and quitted it untouched.—(Linn. Trans., Vol. iv., p. 236.)

In the preceding instances the larva of the *Ichneumon*, when hatched, is solitary, but others are gregarious; the same *Ichneumon* depositing several eggs in the body of a single caterpillar; this is particularly the case with the little *Ichneumons* (*Microgaster glomeratus*), which prey upon the caterpillars which so often devour our cabbage, and which are the offspring of the common white butterfly (*Pontia rapæ*). These caterpillars when full grown creep up the sides of houses to the corners of window-frames, or such like places, where they are ordinarily transformed to a greenish chrysalis, which may often be seen suspended against the wall; but occasionally a great number of small white grubs are observed to burst out of these caterpillars previous to their becoming chrysalides, (which operation, of course, causes the death of the caterpillar) which grubs immediately encase themselves in little oval silken cocoons attached together round the exuviae of their victim, and which resemble a mass of yellow silk. Sometimes, instead of bursting out of the caterpillar, they remain enclosed in it until it undergoes its transformation to the chrysalis state, out of which the *Ichneumons* burst forth in their perfect state. This variation depends upon the species of parasite as well as upon the growth of the caterpillar at the period when the eggs of the *Ichneumon* are deposited in its body; and here we cannot but admire the admirable instinct of these parasitic grubs. Had they as soon as hatched attacked the vital organs of the caterpillar, of course their supply of food would have been destroyed, and they must be left to perish, since they are not provided with feet. Instead of doing this, however, they confine themselves to the fatty parts of the caterpillar; and it is not until these parasitic grubs have nearly attained their full size, that they attack the vital organs of their victim; in order to escape from the body of which, they pierce its skin, and immediately commence the spinning of a cocoon, some bursting out on one side and some on the other; here they immediately commence the spinning of a loose covering drawing the silk out of the spinneret of their lower lip in the same way as ordinary caterpillars; these threads they cross in every direction, forming of them a support for their cocoons, which differ but slightly from those of the silk-worm as regards their consistence, being of a yellow or white colour, according to the species, and so quickly do they complete this operation, that in the course of half an hour each has encased itself in its cocoon. The stems of grasses sometimes bear the cocoons of these insects, and occasionally, but very rarely, a small case is found in the interior of bee-hives, from which an *Ichneumon* has been pro-

duced, which has probably fed upon the caterpillars which devour the wax (*Galleria cereana*). Sometimes these cocoons are banded with different colours, which Reaumur endeavoured to account for by supposing that the nature of the food of the grub would influence the colour of the silk first spun; but this would not account sufficiently for the regular bands often to be seen in the centre of the cocoon. Thus the first silk spun by the *Ichneumon* larva, and which forms the external envelopes, may be white; and the second, forming the inner coating, brown; but if the larva employs this second kind of silk in defending the two ends and the middle of the cocoon, the parts not thus thickened will remain white; and this is what takes place, as may be proved by stripping off the brown part, which is much more solid than the other part—the silk thus employed is very fine and shining, which gives the cocoons a polished appearance. Some species do not, however, form cocoons; but, on the contrary, remain enclosed within the skin of their victim, which, of course, serves them for a covering during the inactive period of their pupa state.

Reaumur discovered a cocoon upon the oak, of a remarkable construction; its form indeed resembled that of the others, and it had a white central band, but it was suspended by a long thread to a leaf or twig; the most singular circumstance connected with it however was, that when detached from the leaf, and laid in a box or upon the hand, it leaped to a considerable height, varying from half an inch to three or four inches. This motion is effected by the inclosed larva making a sudden spring in the same manner as we have described in our account of the motions of the cheesehopper; the sudden unfolding of the body, bringing the head and tail into violent contact with the inside of the cocoon, so as to impart to it a motion operating upon the surface upon which it is placed. But wherefore is it necessary that this larva inclosed in a firm cocoon should possess this faculty of leaping? We may indeed suppose with Reaumur that as the ordinary situation of the cocoon is to be suspended in the air, it may be necessary, in order to regain its position, in case it should be displaced by the wind and lodged on the surface of an adjacent leaf.

It is a circumstance of great interest in an economical view of natural history, that when any particular species of insect detrimental to our vegetable produce increases in numbers so as to be more than ordinarily destructive, its parasites are observed to increase in a much greater degree, so as to prevent the too great multiplication of the former.

These insects are very variable in size; thus some of the British species are amongst the largest of our native hymenopterous insects, and are destined to check the hawkmoths and other large lepidoptera; others, however, are so exceedingly minute as to be visible only when moving upon a window against the light. The latter, whose parasitic habits are identical with the *Ichneumons*, belong systematically to the family *Proclotrupidæ*, and are appropriated to the eggs of many insects. Thus Vallisnieri observed, "I have seen with my own eyes a certain kind of wild flies deposit their eggs upon other eggs, and bore and pierce others with an aculeus, by which they have introduced the egg;" and Linnaeus has accordingly given the name of *Ichneumon ovulorum* to one of these species (or rather to two, since his descriptions are evidently drawn from two distinct species); and out of

a mass of sixty eggs of some lepidopterous insect found upon the osier, and brought to De Geer, not one had escaped the *Ichneumon*. But it is chiefly in destroying the larvæ of other insects that the *Ichneumonidæ* are serviceable, although a few instances are recorded in which the eggs are not deposited until the victim has arrived at the pupa, or even the perfect state. Of those which destroy the larvæ, the majority are internal feeders, but a few have been observed which remain on the outside of the caterpillar until it dies; of this kind are the larvæ of a large orange coloured species, *Ophion luteum*, which feed on the caterpillar of the pussmoth (*Cerrua vinula*). We have already given instances of the attacks of these parasites upon hymenopterous, dipterous, and homopterous insects, in the cases of the wild bees, wheat-midge, and the plant lice. Other species of these orders are similarly infested with *Ichneumonidæ* as well as the *Coleoptera*, but the great mass of the species belonging to the family are appropriated to the order *Lepidoptera*, which they destroy in all their states, and in every situation, whether naked and exposed like the caterpillar of the cabbage butterfly, or buried in the whorls of a leaf like the *Tortrices*, or hidden in the substance of a leaf as the mining *Tineæ*.

But, as if to show the endless convolutions of the great chain of nature, these parasites are themselves subject to the attacks of other and smaller parasites belonging to the same family. Of these, various instances have been well authenticated; and it is remarkable with what admirable precision of instinct these second parasites must acquire the knowledge that particular caterpillars are already attacked by the insects which are to furnish their own progeny with support.

Latreille has divided this family into three principal groups, from the number of joints in the palpi; a character which is, however, not strictly to be relied upon in certain species.

The first group comprises those species in which the maxillary palpi are five-jointed and the labial four-jointed, and the first submarginal cell is united with the discoidal cell, and the second submarginal cell is very minute, being either rounded or square, although sometimes it is entirely wanting. This group comprises the *Ichneumonidæ* of Stephens, a family of such great extent that Gravenhorst has published a description of the European species alone, occupying nearly three thousand octavo pages. Here belong the genera *Pimpla*, having the ovipositor very long; *Cryptus*, *Ophion*, having the abdomen sickle-shaped; *Banchus*, *Hellwigia*, *Joppa*, *Ichneumon*, having the ovipositor not exerted; the abdomen, narrowed, and the base and the head transverse; *Alomyia*, *Pellastes*, and others. Mr. Stephens has described 223 species of the restricted genus *Ichneumon*, in the seventh volume of his illustrations.

The second group comprises those species which have the maxillary palpi five-jointed and the labial four-jointed, and consists of the family or sub-family which we have already described under the name of *BRACONIDÆ*, which see.

The third group comprises those species which have the maxillary palpi six-jointed and the labial four-jointed, and comprises the *Alysudæ* of Stephens, comprising the genera *Alysia*, *Chelonus*, *Sigalphus*, and others.

**ICHYOSARCOLITES.** A fossil genus of shells, of which only one species is known; in general ap-

pearance it may be said to resemble the *Nautili*, *Litula*, and *Spirula* genera; but it has peculiarly distinct characteristics, and merits the honour of constituting a genus.

**ICICA** (Aublet). A genus of South American trees belonging to *Decandriæ*, and to the order *Terebinthaceæ*. Generic character: calyx four-cleft persisting; petals broad at the base, seated below the germen; spreading stamens inserted into the bottom of the calyx, under a circular disk; filaments shorter than the corolla; anthers oval, erect, and two-celled; style short; stigma two-headed; drupe two-valved; nut double. The fruit of one of these trees is very fragrant, and used as a perfume. The wood of *I. altissima* is very durable, and used for making household furniture, boats, &c.: as stove plants they succeed with the ordinary management.

**IGUANA.** A genus of saurian reptile, and the one which is perhaps most generally characteristic of those animals which are known by the general name of lizards, though Cuvier makes it the name of his third family, *Sauria*. The iguanæ, properly so called form the second section of the family, and are distinguished from the first family by having teeth on the palate. The general characters are: the body and the tail covered with small imbricated scales; a range or crest along the back, consisting of spines, or of scales, which are erected, compressed, and pointed; under the throat there is an appendage of skin, forming a sort of ruff in that part, the edges of which are supported by a cartilaginous production of the os hyoides; their thighs have a range of tubercles, like those on the true lizards; each jaw is furnished with one row of teeth, which are compressed, triangular, and trenchant; and there are besides two rows of small teeth on the posterior margin of the palat. There are several species, and as is the case throughout almost the whole class of reptiles, there is not a little confusion about the history of at least some of them. Those which strictly belong to the genus are, we believe, all inhabitants of the American continent, and chiefly of the tropical part of it, though some are found, at least, as far north as the southern parts of the United States.

**COMMON IGUANA** (*I. tuberculata*). This species is found in tropical America, especially in Guiana, and the countries westward to the shores of the Pacific; it grows to a large size, being in general three feet long, and specimens measuring five feet are not rare. The shape of the animal is not considered very handsome, in consequence of the prejudice which exists against the whole race of saurian reptiles, which are all very harmless creatures, with the exception of the larger ones which inhabit the waters; the upper part is greenish yellow, marbled with pure green, and having the tail annulated with brown; but the colours are variable, according to the position of the light, and the state of excitement in the animal, being blue, violet, green, and even black; the under part is of the same colour with the upper, but much paler; there is a crest of large spiny scales all down the back; a large plate on each side of the head, at the angle of the jaws; the sides of the neck are covered with pyramidal scales more thinly set than the rest; and the margin of the enlargement, or colour under the throat, is furnished with the same kind of scales as those on the ridge of the back. This species is very common in all the warmer parts of America; and it is not only very inoffensive, but of

considerable value to the inhabitants. It is generally found among, or upon, the branches of trees, but it occasionally takes to the water. It is understood to be in a great measure, if not wholly, vegetable in its feeding, living upon fruits, seeds, and leaves. The females lay a great number of eggs, which they deposit in the sand to be hatched. These eggs are about the same size as those of the pigeon; but, as is the case with the eggs of most reptiles, the two ends are alike in form. These eggs are accounted a great delicacy, and eagerly sought after on that account. The flesh is held in nearly equal esteem; and in consequence of this the animal is very much hunted. It is difficult to kill, which is a very common property of reptiles; and its skin is not easily pierced by a musket bullet, because if it strike obliquely, it glances off. When attacked, they assume a formidable, though not a dangerous aspect; they open their mouths, vibrate their tongues with rapid motion, inflate their throats, and erect their crests, while their eyes glance with the brilliancy of live coals. All this, however, is a demonstration for defence, and not for attack; for though they possibly may add insects to their vegetable food, there is no reason to suppose that they attack any animal of even the most moderate size. It very often happens, indeed, that the attitude of the iguana, and the peculiar sound which it gives, when alarmed by its enemies in the woods, both warn man of the danger to which he is exposed, and betray themselves to him as a prize.

**SMOOTH-NECKED IGUANA** (*I. nudicollis*). This species resembles the last-described in many respects, but it wants the large plates on the cheeks, and the pyramidal scales on the sides of the neck. The upper part of the head is covered with convex plates, the occiput is tuberculated, and the collar is smaller than the one last mentioned, and has only a few tubercles on the anterior margin. Some describers have represented this species as being a native of the east as well as of the west; but that is a mistake, for it occurs in no country except tropical America, and the West India Islands.

**HORNED IGUANA** (*I. cornuta*). This resembles both of the preceding in most of its characters; but it is distinguished by an ossious point of bone which stands up between the eyes, and is the part from which the animal gets the incorrect name of horned. There are two projecting scales also in the nostrils, but there is no plate on the cheek, and no tubercles on the neck. The scales along the edges of the jaws are, however, furnished with an elevated boss in the middle of each. This species is found in the West India islands, and especially in the island of St. Domingo. Its food consists of vegetable substances, insects, and small birds. The negroes hunt it with great avidity for the sake of its flesh; and the maroon dogs, or blood-hounds, of the country, which used to be so cruelly employed against the oppressed people of that and some other of the islands, are now employed in hunting the horned iguana. It is a day animal, and while the light continues, it follows its prey with wonderful assiduity; but during the night, it remains concealed in the holes of the rocks. During the rainy season it retires, and becomes nearly, if not altogether, dormant.

**CAROLINA IGUANA** (*I. Aychlura*). This species is found further to the north, and, like the last-mentioned one, it passes the inclement season in a state of repose. It has no large plate on the cheek, nor spines

on the neck; but the plates on the tail form a sort of armour, from which the animal gets the trivial name. It does not appear to differ much from the others in its manners.

**BLUE IGUANA** (*I. carulea*) is wholly of a violet blue colour on the upper part, and the same colour, but smaller, on the under. In size, it is considerably less than any of the former, and the scales which form the dorsal crest, or ridge, are much less produced. In other respects, it scarcely differs from the rest; and therefore Cuvier is probably right in regarding it as only a coloured variety. There is not indeed a great deal of difference between the species of iguana, and there is a similar correspondence in their manners.

Many other saurian reptiles, besides those which we have enumerated, have been described as iguanas; but there are sources of error connected with the lizard, against which it is not easy to guard, at least on the part of those who take museum specimens as the foundation of their arrangements, because lizards change very much after they are dead, and the bodies of many are tender and easily mutilated.

**ILEX** (Linnaeus). A fine useful genus of evergreen trees and shrubs, commonly known by the name holly. See **HOLLY**. They belong to the fourth class of Linnaeus, and to the natural order *Celastrineæ*. Europe is the native clime of the common holly, but there are various species found in many other parts of the world.

**ILLICIUM** (Linnaeus). A genus of Chinese and American evergreen and deciduous shrubs, belonging to *Polyandria Polygynia*, and to the natural order *Magnoliaceæ*. Generic character: calyx from three to six sepaled, deciduous, sepals unequal; petals nine, or more unequal; stamens inserted into the receptacle; filament very short; anthers erect, oblong, and emargined; style very short; stigma lateral oblong; capsules several, disposed in a circle, leathery, opening at top, and containing each one seed.

The plants of this genus are called aniseed-trees, from their fine aromatic scent. The dried capsules are called *five-fingers* in China, and in commerce *Chinese anise*. When the plant grows naturally, the capsules are used as a condiment, and chewed after dinner as a sweetener of the breath. The bark, when finely powdered, is used by the public watchmen in Japan to make a timekeeper, or instrument for measuring the hours, in order to direct when the public bells are to sound. The *I. anisatum* is a favourite and rather hardy greenhouse plant, grows well in loam and moor-earth, and may be propagated by cuttings.

**IMPATIENS** (Rivinus). A genus of curious annuals. These plants are natives of many different parts of the world. The flowers are pentandrous, and the genus ranks among the *Balsamineæ*. The plants have received their generic name from the elastic properties of their capsules, to scatter the seeds on being touched. One of them indigenous in England is called *Noli me tangere*, or Touch-me-not. They were formerly associated with the balsams.

**IMPERATA** (Cyrilla). A genus of plants belonging to the *Gramineæ*, with elegant feather-like spikes of flowers. Its strong reeds are used for many purposes in the south of Europe.

**INDIAN BAY**. This plant is the *Laurus Indica* of Linnaeus.

**INDIAN CORN** is the *Zea mays* of Linnæus. This is a most important species of corn in America, and other countries suitable to its production. Some of the hardier varieties have been tried in this country, and, by some farmers who attended to its culture, with considerable success. But although the produce is great, both in grain and straw, it is not equal, all things considered, in value to our common horse bean, and certainly not to be compared with our common wheat as a bread corn. It has been so long known in our gardens, and is now so frequently seen in our fields, that any detailed account of the plant is unnecessary.

**INDIAN CRESS** is the *Tropæolum majus* of Linnæus, a well-known ornamental plant, cultivated not only for the beauty of its flowers, but for its seed-pods as a pickle.

**INDIAN FIG** is the *Opuntia ficus indica* of Haworth.

**INDIGOFERA** (Linnæus). A genus of herbs and shrubs belonging to *Diadelphia*, and to the natural order *Leguminosæ*. The *I. tinctoria* is the plant whence the valuable dye is extracted, on which account it is extensively cultivated in India, and other parts of the world.

In the Delta of the Ganges, where the best and largest quantity of indigo is produced, the plant lasts only for a single season, being destroyed by the periodical inundations; but in the dry, central, or western provinces, it lasts two years, one, or even two, offset crops being obtained; and owing to this circumstance, the planters in the latter situations are enabled to furnish a large supply of seed to those in the former. The seeds are sown in drills, a foot apart, during the rainy season, and kept free from weeds. In two or three months the crop is fit for cutting, but the plants must not be allowed to flower, otherwise the foliage becomes hard and unproductive; and it should be cut in wet weather, for if the season be too dry the stools will not spring again; hence from these and other circumstances, the produce is precarious. When cut, the herb is steeped in vats; and after being well macerated, and the colouring matter extracted, the liquor is drawn off into other vessels, in which it undergoes the peculiar process of beating, to cause the fæcula to subside. The fæcula is subsequently collected, and transferred into a third set of vats, where it remains for some time before it is strained through cloth bags, and evaporated in shallow wooden boxes placed in the shade. Before it is perfectly dry, it is cut into small pieces an inch square, and is then packed in barrels, or sewed up in sacks for sale.

It appears pretty certain that the culture of the indigo plant, and the preparation of the dye, have been common in India from a very remote period. Pliny mentions it under the name of *Indicum*, and states that, when diluted with water, it produces an admirable mixture of blue and purple colours. He knew, also, it was the produce of a vegetable, but was much mistaken as to its mode of preparation. The indigo plant, in its natural state, is innoxious; but indigo, when prepared, is a dangerous poison. The chemical changes which take place during the process of preparation, are extremely curious. Two or three species of this genus are kept in our stoves, and are easily propagated by cuttings.

**INFEROBRANCHIATA**, in modern malacology, is the fourth order of De Blainville's system; it

includes all such molluscs as have branchial organs of respiration, lamellarly disposed beneath the salient edge of the mantle; the body is always naked, oval shaped, and more or less tuberculated. This order merely contains the genera *Phyllidia* and *Linguilla*.

**INGA** (Plumier). An extensive genus of evergreen shrubs and trees, chiefly natives of South America, belonging to the natural order *Leguminosæ*. Generic character: flowers polygamous; calyx five-toothed; corolla of five petals, or parts; stamens united at the base, and protruding; style simple; pod compressed, two-valved, seeds pulpy or farinaceous. The genus has been separated from *Mimosa* to which it bears a resemblance, and may be treated in the same way as the stove mimosas.

**INOCARPUS** (Forster). A fruit-tree, common on the islands of the South Sea; hence called the Otaheite chestnut. It belongs to the natural order *Sapoleæ*, is kept in our stoves, and propagated by cuttings.

**INOCERAMUS** (Brogniart). A mollusc only known in a fossil state; of course the animal is totally unknown; in its general appearance it resembles the *Ostracæ*, but more nearly the genus *Gryphæa*. Three species are enumerated by De France.

**INSECT.** The ordinary English name given to the individuals composing the most extensive class of animals to which Linnæus and the older authors gave the name *Insecta*, a word derived from the Latin, and signifying an animal cut or divided into numerous parts or segments, and equally applicable to various species which have the chief divisions of the body connected together by slender points of attachment; the legs in like manner are inserted or composed of various articulations. It is not surprising that these characters should have attracted the notice of the earliest naturalists, and we accordingly find the group of insects established by the first writers upon zoology; not indeed with that precision of definition which the anatomical researches of modern authors have enabled us to apply to the group, but, on the contrary, united with many other small invertebrated animals, which, even in the present day, are considered as insects by ignorant persons. On examining the body of an insect, we find it externally covered with a strong scaly coating, which, when internally examined, is found to give support to the muscles and other organs, thus becoming as it were an external vertebra; but the observation will immediately occur that the horny nature of this external covering must necessarily prevent the growth of the animal; and this would certainly be the case were not the difficulty obviated in a manner as remarkable as it is perfect, namely by the periodical shedding of the external envelope, forced open as it were from time to time by the internal organs, which have increased in volume since the preceding moulting, owing to the quantity of food taken by the creature. This shedding of the covering of the body is very variable in its effects upon the various groups of insects, in some consisting of a mere throwing off of the outer envelope, without any other change being effected, save that of an increase of size; in others, however, an increase of limbs is obtained; and in some, an entire change in the form of the body is effected, and organs of flight acquired. These latter changes are termed metamorphoses or transformations, and are more especially applicable to the winged groups of insects. Another important character distinguishing this tribe of animals is to be

found in the highly organised structure of the eyes in the majority, although in some the organs of sight consist only in a number of small tubercular lenses, which are moreover found in some species which also possess the compound or faceted eyes. The head is also furnished, in the majority of the tribe, with a pair of articulated organs, varying infinitely in their construction, termed antennæ, of which the precise uses have not hitherto been decidedly ascertained. Such are the leading characters of the great mass of animals to which Linnæus gave the name of *Insecta*, but which Latreille has changed into *Condylopa*, from the articulated structure of the legs. The anatomical investigations of foreign naturalists, about the commencement of the present century, threw a great light upon the real nature of the various groups of Linnæan insects, and upon the respective value of the characters by which the orders into which they had been divided were separated from each other. It was thence at once discovered, that, although the winged orders of insects established by Linnæus were nearly allied amongst themselves, the wingless order (*Aptera*) contained a mass of objects having the most discordant organisations, and which, when properly examined, were proved to be characteristic of groups of higher rank even than the winged orders themselves. In this manner the apterous Linnæan genera, *Cancer*, *Monoculus*, and *Oniscus*, were formed into the class *Crustacea*; *Aranea*, *Scorpio*, *Phalangium*, and *Acarus*, into that of *Arachnida*; whilst *Scolopendra* and *Julus*, as a group named *Myriapoda*, *Lepisma* and *Podura*, under the name of *Thysanura*, and *Pediculus* under that of *Anoplura*, have been alternately raised to the rank of classes, or regarded as orders in the classes *Arachnida* and winged insects, to which last it has been proposed to restrict the name of insects. But this is a step to which we would strenuously object. We would not willingly be charged with veneration for the works of our predecessors in science merely because they happen to be old; but we do object to the spirit of innovation which cannot distinguish between what is old and what is good; and if the Linnæan group of insects is to be retained, as we submit that it ought to be, as one of the chief divisions of animals, we would certainly retain for it the name of *Insecta*, which so peculiarly refers to the great character of the group, in preference to that of *Condylopa* proposed by Latreille. It may indeed be said that it is not proper to apply the name of insect to a crab or a lobster, but they are as strictly insected animals as a bee or a beetle; and it may be said, that if we apply the name in this general manner we shall need some other name to distinguish the true winged insects from the *Crustacea* and *Arachnida*, and this it must be admitted is the fact; and the question then arises shall we, in order to obviate this difficulty, throw ourselves into the other dilemma, and take away the name of *Insecta* from insected animals. We, however, see no occasion for this step. Systematically, the winged insects may be named *Ptilota*, as proposed by Aristotle, and the Linnæan insects will retain their name of *Insecta*, divisible into four classes, namely, the *Crustacea*, *Arachnida*, *Ametabola*, and *Ptilota*; the first two of which are treated upon under their respective heads, and may therefore be dismissed from our future consideration. The third is a class the limits of which have been by no means decided by entomologists, Dr. Leach placing in it only the hexapod lice (*Pediculi*), and the spring-tailed

insects (*Lepisma* and *Podura*); whilst MacLeay has added thereto the *Myriapoda*, consisting of the two orders *Chilopoda* (*Scolopendraz*) and *Chilognatha* (*Iuli*), as well as certain vermes. It would occupy us too great a space to enter into the considerations requisite for the investigation of the correctness of these views. We shall therefore (having already treated upon the last named insects in their alphabetic order) now confine ourselves to the true metamorphic or winged insects, or the *Ptilota* of Aristotle. In our article ENTOMOLOGY we have entered into some general considerations, in order to prove that the study of this branch of zoology is attended with great interest, resulting from the countless tribes of insects, their various forms, singular instincts, &c. With the further view of enticing the reader to follow us in our necessary details of the structure of these tribes, we now propose to renew the subject, by laying before him a short notice of the benefits and injuries resulting from insects to mankind, in order to prove to him that these little creatures are not so insignificant as he might be induced to believe them to be, but are very capable of rendering themselves obnoxious to him, should he be disposed to consider them as not worthy of his attention, or, on the contrary, of being rendered highly beneficial.

Of all animals, insects are unquestionably the most obnoxious to mankind, either personally or from their attacks upon his property, their minute size ensuring them success in their assaults, and scarcely permitting the possibility of extirpation. On the other hand, the benefits which he experiences, either directly or indirectly, are scarcely less extensive. If we would, therefore, endeavour successfully to combat the former, it can evidently only be done by the acquisition of a knowledge of their habits in every state of their existence, and in this point of view the study of entomology becomes of the highest importance. Let us take, for instance, the turnip-fly, of which we have given an account in our article HALTICA, and here we find that all the numerous investigations of the committee of the Doncaster Agricultural Association proved useless, because the natural history of the insect itself was not ascertained. In like manner, it must be equally evident that the diffusion of similar knowledge, and more especially inquiries into the chemical properties of many insects hitherto considered useless, might be the means of adding considerably to the list of benefits conferred by insects on man.

Of winged insects very few species have hitherto been found serviceable as articles of food. It is true, that in the deserts of Asia and Africa, where the locusts acquire a large size, these insects are employed, when dried and preserved, as food. The writer has tasted locusts thus prepared, and has found them not unpalatable, but they are said to possess but very little nutritious quality, and to produce disease when too much is eaten. The larvæ or grubs of many large beetles are also devoured by the negroes of India and America; and even the luxurious Romans were exceedingly fond of a large fleshy grub, which they called *cosus*, and which is supposed to have been the larva of the goat moth (*cosus ligniperda*). In like manner, the white ants are devoured by the savages of Africa and America; whilst the great quantity of honey annually consumed in every quarter of the world is sufficient to prove that, in this point of view, insects are highly beneficial. It has also been re-

cently discovered, that the manna which, it will be remembered, served the Israelites for food during their passage through the Wilderness, is but the concentered juice of an Arabian tree (*Tamarix mannifera*), which is caused to flow by the puncture of a small species of *Coccus*, which the celebrated Prussian entomologist, Dr. Klug, has recently described and figured under the name of *Coccus manipularis* in his splendid work upon the insects of Arabia, and to whom the writer himself is indebted for specimens of this interesting insect. In medicine insects are also of great service. Of these the *Cantharis vesicatoria* is the most important, and of the properties of which an account will be found in our article CANTHARIDÆ. Numerous other species were formerly introduced into the Pharmacopœia, but they have gradually been disused. In a commercial point of view, silk, chermes and cochineal are some of the most important products. Of the former we shall give a detailed account in our article upon the SILKWORM; and of the latter a description has been published in our article COCCIDÆ. There are many other insects which construct silken cocoons, and emit various coloured dyes, and which it might be very serviceable to endeavour to introduce as well as the true silkworm of the *coccus cacti*. Gumlac also, wax and ink-galls, are insect productions of too great importance to be passed over without notice. But there are other classes of bene-

The Ink-gall insect, and the insect by which it is produced.

fits resulting from the relations of insects with other organised beings. These, although less directly affecting man, ought not to be overlooked in a general survey of the economy of nature. Suppose the race of insects to be entirely annihilated, and then observe the thousands of ills which would inevitably result from the putrefying masses of animal and vegetable productions, and which are now, as it were, reduced to their native elements solely by the interference of the insect tribes. The entire tribes of *Silpha*, *Necrophagi*, *Dermestes*, *Nitidulæ*, immediately fall upon the dead carcasses of animals, devouring the flesh, and accelerating the dissipation of the putrid mass, and these, assisted by myriads of flies, which deposit their eggs in the decomposing body in such immense numbers, succeed, in a very few days, in reducing the carcass to a mere skeleton. In like manner, the *Geotrupidæ*, *Histeridæ*, and many other insects, are equally serviceable (as we have already stated in our articles upon these groups) in disseminating the excrements of animals, and rendering them serviceable to the agriculturist; whilst the tribes of insects which feed upon decaying vegetable matter are even still more numerous. As serving for food to some of the higher animals, as fish, birds, some of the smaller mammalia, &c., insects are eminently serviceable in the scale of the creation. Amongst birds, the shrikes, and the genera *Sylvidæ*, *Motacilla*, *Anthura*, *Certhia*, *Muscicapa*, and *Hirundo*, as well as

the cuckoos and pies; and amongst quadrupeds, the genera *Stenops* and *Otobenus*, which feed upon grasshoppers, the bats, shrew, hedgehog, mole, and especially the genus *Myrmecophaga*, which derive their sole nutriment from insects. Many species of insects are equally serviceable in destroying other noxious insects. Of these the tribes of predaceous beetles, sawwasps, ants, dragon-flies, spiders, &c. are to be noticed, but more especially the larvæ of the ladybirds (*Syrphidæ*) and golden-eyed flies, which destroy myriads of plant lice. All these, however, yield to the *Ichneumonidæ*, which annually destroy more caterpillars than the whole tribes of insectivorous birds. We must refer to our article upon this family to show the almost universal dominion of these parasitic tribes. In the last place, we have to notice the great services rendered by insects in effecting the impregnation of plants, in many of which the position of the sexual organs is such, that, were it not for the intervention of insects, especially bees, butterflies, &c., which, whilst seeking food for their own nourishment, unconsciously perform a most important office, of which we have already, in our article CECDOMYIA, mentioned an instance; and in our article CYNIPIDÆ we have noticed the effect of insects in effecting the more rapid ripening of the fig, by the process termed capricification by the inhabitants of the Levant.

It is, however, necessary for us now to reverse the picture, and to observe, that if insects are capable of being serviceable to mankind, other species are not less injurious to him and his property. We will first notice such species as possess a direct influence against mankind. Of these the various species of lice, the flea, jigger, and the bed-bug, are pre-eminently obnoxious. Besides these, we are condemned to suffer from the occasional attacks of multitudes of other species, which at all hours of the day cease not their tormenting powers. Moreover, the hotter the climate and the period when the body requires the greatest portion of rest, the more numerous are the hordes of our insect enemies. The *Tabani*, *Stomoxæ*, *Asili*, are all highly irritating; but all these yield to the gnat and the mosquito, which are sometimes so annoying and so numerous, that their victims have sunk under their attacks. There is also another little insect, which, in the autumn, is very annoying to persons who walk about the fields, and which is so minute that it escapes observation. It is called the harvest-bug, but is in reality one of the *Acaridæ*, of a red colour, its mode of attack being to insinuate itself into the flesh of the legs, where it causes an intolerable itching, and raises the most irritating sores. An analogous species inhabits the West Indies, where surgical operations are required to dislodge it, causing, if neglected, abscesses, gangrene, and even death. The name of *Scholechanis* has been applied to a disease in which the larvæ of various species of insects are found in the human body, but these appear to be entirely accidental cases wherein these larvæ have been injected. A species of (*Estrus*, in like manner, has been found to be parasitic within the body of persons residing in the tropics, but this (although it has received the name of *Estrus hominis*) we should be rather induced to regard also as an accidental locality selected by the insect, instead of its real habitat. There is another tribe of insect enemies whose attacks are not less annoying, although not resulting, like the former, from a desire to feed upon our bodies. Here are to be ranked the bees,

wasps, and other insects provided with poisonous stings, which, however, they seldom employ except in their own defence, or to resent injuries offered to themselves. Here also may be added the spiders, whose powerful jaws are equally provided with a poisonous fluid, as well as the scorpion, whose long and jointed tail is defended at the tip with a powerful sting. Other insects are to be ranked amongst our minor miseries, namely, such as, by the emission of a caustic, or disgusting fluid, operate strongly upon our olfactory nerves. But the tribes of insects which prey upon our cattle is equally numerous, including fleas of different species, ticks, gadflies, forest flies, and especially the remarkable family of *Estrideus* flies, the larvæ of some of which are ordinarily termed bots. Of the latter we have already given an account in our article BOT. In like manner, our poultry and our bees are subject to the attacks of various insects, of some of which accounts will be found in our articles upon the DEATH'S-HEAD MOTH and the GALLERIA.

It is not, however, upon ourselves and living animals that the ravages of insects are confined, almost every species of property being in some measure or other liable to be injured by them. Our clothes, and other woollen productions, are devoured by the larvæ of various species of clothes' moths, which not only feed thereon, but also form for themselves coverings of the same materials; and the richest furs are subject to the attacks of a similar insect; whilst our museums are equally ravaged by the *Dermestes* and *Anthreni*. Our furniture is often completely destroyed by the timber-boring beetles and death-watches (*Anobium*); and some species of white ants, in warm climates, are so destructive in this respect, that if a chair or table be suffered to remain for a time in the same situation, the interior substance will be completely consumed, nothing remaining but the outside shell, which the insect has the instinct to leave entire. The last named insects may indeed be regarded as amongst the most destructive of our insect enemies, since they scarcely leave any article untouched. Ants also are, in warm climates, almost as destructive; and even in our own country, one of the smallest species of ants, *Formica unifasciata*, has increased to such an extent in certain parts of London, and some other towns, devouring all kinds of articles, that the inhabitants have been compelled to quit their abodes.

Our provisions are also not less liable to the attacks of insects; bread and flour are devoured by the blattæ and meal-worms, and we have seen ship-biscuit swarming to such a degree with the grubs of a species of *Anobium* as to be worse than useless. The *Dermestes* feed upon our dried meats. Cheese is attacked by mites; and the cheese-fly, the grubs of which are termed cheese-hoppers, from their singular motions which we have already described in our account of this insect. Our granaries are ravaged by the corn weevil and by the larvæ of a species of tinea; but if we turn our attention to the species of insects which attack such living vegetable productions as are most gratifying to the lip of mankind, we find the catalogue woefully augmented.

We need scarcely mention the locust as being the most redoubtable of our insect enemies in this respect, although, fortunately for our country, their ravages are here unknown, except by description. Our wheat whilst in blossom suffers from the attacks of the Hessian fly and *Cecidomyia tribici*, of which we have

already given an account, whilst its roots are devoured by the larvæ of the *Zabrus gibbus*, which sometimes, as in the year 1812, near Halle in Germany, is produced in such numbers, that whole corn fields are entirely destroyed. The larvæ of some of the *Elateridæ*, known by the ordinary name of wire-worms, also attack its roots, as well as the roots of various other garden plants and culinary vegetables. The grubs of the cockchafer in like manner often do much injury by devouring the roots of grass; as do also those of the *Tipulæ*. Of the former, an instance is recorded by Kirby and Spence, in which all the fields of a farmer near Norwich were entirely destroyed, and as many as eighty bushels were collected by him and his men. Various other esculent roots are also devoured by the larvæ of other insects; amongst which the damage occasioned by the onion-fly (*Anthomyia ceparum*), the grub of which destroys the plant when still very young, is, perhaps, the most detrimental. In like manner the stems and the pith of trees and plants are equally subject to the ravages of insects, amongst which may especially be noticed the *Bostrichidæ*, of whose proceedings under the bark of trees we have already given a detailed account. The gigantic larvæ of the longicorn beetles, goat-moths, *Siricidæ*, &c., are not less destructive by boring through the solid wood of various trees; whilst an ant (*Formica saccharivora*), which takes up its abode in the stem of the sugar-cane, has proved at certain periods in the highest degree obnoxious. But it is upon the leaves and young buds and stems of plants that insects are the most detrimental in their attacks. Of these the turnip-fly, *Halicta nemorum*, and some other species hold the foremost rank. Entire and extensive families of beetles (*Crioceridæ*, *Chrysomelidæ*, &c.), are similarly employed in devouring the leaves of various plants, as well as the numerous species of saw-flies; but it is amongst the *Lepidoptera* that this species of injury occurs in the highest degree, whole forests being sometimes entirely defoliated by various species. In like manner the flowers and fruits of various plants are subject to similar devastation by insects. It would, however, require an entire enumeration of vegetables and their attendant species of insects, in order to lay before the reader a complete account of the ravages of insects upon our vegetable productions; since it is to be observed that, for the most part, the latter are destined by an all-wise Creator for the support of the former. Their ravages, therefore, which man regards as injuries towards himself, are but the natural result of the ordinary workings of the economy of nature. A few observations upon this branch of the subject, and with reference to the employment of remedies against the attacks of these noxious insects, will not be considered out of place. One of the most common, and at the same time most weighty charges brought against the entomologist is, that whilst he bestows endless labour and trouble in collecting and preserving the various species of insects, his attention is never, or but very rarely, directed to inquiries into the most effectual remedies against those insect scourges which nature has inflicted upon our vegetable productions. He is told over and over again, that to make the science which he cultivates more beneficial to society, and thereby more generally known, a share, at least, of his attention must be occupied in prosecuting experiments for the purpose of discovering how this or that insect enemy may be combated in the most suc-

cessful manner. And, indeed, it must be admitted, that this is a charge too well founded, although, perhaps, a few observations may convince those who are the most ready to bring it forward upon every opportunity, that it may be greatly palliated. In the first place, therefore, it may be urged, that these destructive insects, appearing as they do in occasional seasons in vast profusion, are produced in such myriads for some wise purpose, which we may not be permitted to understand. They, like the locusts, of which so splendid a poetical description is recorded in the second chapter of the prophet Joel, form a portion of the army of the Almighty wherewith he scourges the nations; and, although the scientific researches of mankind might discover means of destroying in some degree, these hosts, it may perhaps not unreasonably be supposed either that he would not be allowed to frustrate the designs of Providence, or that, if this evil were removed, others perhaps more weighty might arise in their stead. In the second place, the minuteness of the size of these creatures presents an almost insurmountable barrier against those delicate inquiries and examinations of them, during every state of their existence, by which alone we can arrive at a knowledge of the real nature and cause of the mischief, and be thereby, and thereby alone, enabled to judge of a suitable remedy. In the third place, the want of sufficient opportunity is not the least objection which may be brought against the charge. It must be admitted, that no effectual check can be given to the ravages of any species of noxious insect until its entire habits and economy have been ascertained. Thus far in the inquiry is the strict province of the entomologist, whose attention ought to be directed from day to day, and from year to year, not to isolated spots of ground, but to whole acres, more especially with reference to the peculiarities of seasons, and to atmospheric changes; but here we have only gone halfway. It now becomes the province of the agriculturist to discover a remedy, since it seems equally clear that this ulterior branch of the inquiry can only be prosecuted effectually by persons perfectly conversant with the chemical nature of soils, the action of various ingredients which may be employed as remedies, not only upon insects themselves, but also upon the plants which may be attacked. Such persons too are alone able to judge of the practicability of the application of the proposed remedies, since it would be useless for an indoor entomologist to endeavour by experiment to discover remedies which, when discovered, cannot be adopted from the great expense of the article itself, or the impossibility of applying it, or the liability of the destruction not only of the insect, but also of the plant itself, and even instances of the latter description have been recorded.

Hence we must evidently look for the discovery of the most efficient remedies to persons who, residing in the country, are the best enabled to obtain a knowledge of the economy of these destructive insects, founded upon the most general and practical modes of examination, and who unite the entomological knowledge requisite to trace most effectually their habits, with a perfect and scientific knowledge of the true principles of agriculture. Thus it seems undoubted, that this want of sufficient opportunity for investigation has hitherto proved one of the greatest barriers to our proposing satisfactory remedies against the ravages; and knowing, as we too well know, that

the study and investigation of this branch of zoology has hitherto been almost uncultivated amongst us, it is not, perhaps, surprising that so little has been done. The observer of insects has, indeed, proposed remedies which the agriculturist cannot adopt; and the agriculturist on the other hand, ignorant of the nature of insects, has pursued the very plan which has been the most congenial to the habits of the insects which he wished to destroy; as in the case of the French gardener, mentioned by Reaumur, who thinking to destroy the caterpillars of the cabbage-moth, buried them just at the time when they were themselves on the point of going into the earth to change to chrysalides\*.

Thus have we endeavoured to show not only that in respect to their various relations towards mankind insects possess considerable claims upon our attention, but have also been anxious to prove that a knowledge of the habits and economy of insects in their various states, cannot fail to be highly advantageous, and, in fact, absolutely necessary, both in order to enable us to discover suitable remedies against the attacks of obnoxious species upon ourselves or our properties, and also as tending to the probable discovery of other species equally beneficial with those already employed by man. It therefore now becomes necessary for us to detail such particulars relative to the various stages in the lives of insects to which we have already alluded, as are essential to be known, in order to obtain a correct notion of their habits in these various states.

We have already stated that the subjects of our present inquiry, as restricted by the establishment of the other modern classes separated from the Linnæan insects, comprise those species of annulose animals, which are provided in their perfect state with six jointed legs and two antennæ, and which are subject to a series of transformations of a variable degree, by means of which, in almost every species, organs of flight are developed; the latter characters constituting, in fact, the grand characteristic of the class *Ptilota*, or winged insects. Hence it will be evident, that an inquiry into the nature of these changes, and a consideration of the peculiarities exhibited by insects during their progress towards maturity, constitute the first step, and are, in fact, the necessary commencement of our inquiries into the nature of insects.

There are, it is true, inquiries of a preliminary nature, having reference to the entire sub-kingdom of annulose animals; such, for instance, as the question of typical priority of the various classes, the points of connection existing between them, and the other animal sub-kingdoms; the supposed uniformity in the organization of the various parts of the mouth, so ingeniously and elaborately worked out by Savigny, Latreille, &c., or the attempts made by various authors to reduce their varying structure to one typical form. These inquiries, however, which are the especial province of the comparative anatomist, would occupy too great a space in an essay like the present, and could not, in fact, be treated in a satisfactory manner, or even be rendered intelligible to the general reader, without an elaborate series of figures and descriptions. Hence we must refer our readers to the works of these authors, and more particularly to the work of M. Straus Dürckheim, upon the general

\* From the Magazine of Natural History.

principles of the comparative structure of annulose animals. Leaving, therefore, these abstruse but highly interesting and philosophical topics, our present inquiry will be directed in tracing the insect through its various stages; first, to a general consideration of the principles which regulate the metamorphoses of insects; and secondly, to a review of the peculiarities exhibited by these animals, in their passage to the perfect state. To these will naturally succeed, thirdly, a general view of the insect structure, especially as exhibited in such perfect state, both externally and internally; fourthly, a sketch of their physiological and instinctive properties; and we shall terminate our inquiries by, fifthly, a sketch of the classification of the winged insects.

Section I.—On the principles which regulate the metamorphoses of insects. One of the most remarkable peculiarities connected with the progressive development of animals, is that for the discovery of which we are indebted to the physiological researches of modern comparative anatomists; namely, that animals traverse through a certain series of grades of development, by means of which they ascend from the first simple beginnings of life to its highest perfection; these various grades being evident representatives, or analogies of the perfect states of the still more inferior types of animals. This singular and startling peculiarity is not a fanciful theory, but has been the result of the most accurate application of the facts, obtained by the aid of comparative anatomy. And the consequent result of this principle is, that the higher the animal in the chain of creation, the greater number of grades has it to traverse. Not that by this assertion it is intended that one animal was, at any period of its existence, a distinct animal, but simply that certain types of form, or various peculiarities of certain internal organisations, which are characteristic of the perfect state of the more inferior animals, are reproduced in those of a higher rank, previous to the arrival of the latter at the precise type which is their own. "No one," observes Burmeister, "who speaks of the embryo of man passing through the lower grades of the animal kingdom, can have imagined that man, at any period of his embryo life, was ever an infusory animal—polypus, muscle, snail, worm, crab, spider, insect, fish, turtle, snake, lizard, and bird; but the assertion is nothing more than that man has once, in the progress of his development, been upon that grade upon which the several classes beneath him remain stationary, in the progressive development of the entire animal kingdom." Now, the most general form of insects is that of an articulated elongated body; but previous to its bursting into life, whilst yet in the egg, its organisation represents that of the most inferior animals, having then no other organs than those of nutrition; when this release is effected, we find the animal has now ascended to the lowest types of the articulated structure; the earthworm and the leech are strictly represented by those vermiform grubs which have no distinct head, and which belong to the order of two-winged flies, *Diptera*. Will it, we ask, be asserted, that this is but a fanciful idea, confirmed, as it is, by the fact, that the dipterous insects, when arrived at the perfect state, are the least perfectly developed of all the winged insects. Another grade is attained by those larvæ, which, although vermiform, are furnished with a distinct head, as the larvæ of the *Hymenoptera*,

which represent the water *Nais*; a third grade is exhibited in those larvæ which have the body furnished with lateral gills, and reside in tubes; and a still higher is reached by those larvæ which, like the *Nereis* and *Aphrodita*, belonging to the *Annelida*, have a distinct head and legs on the under side of the body. In the following or pupa state, we find some pupæ, as those of the gnats, breathing like the crustacea, by gills; others, as those of the moths, buried under ground, like the *Myriapoda*; whilst the pupæ of butterflies are suspended like the *Arachnida*, in the open air. The above, which is a brief abstract of the analogies exhibited by Dr. Burmeister, do not, it must be admitted, in some respects possess equally strong grounds for adoption; but the view of the subject is so novel, that much necessarily remains to be discovered; and what has yet been adduced, can only be regarded as an approximation towards the truth; neither can this view of the subject be fully confirmed, until by the aid of comparative anatomy, and by an accurate investigation of the nervous and other systems of animals, the rank of each principal division in the scale of creation has been definitely settled. Still, however, sufficient has been advanced to prove that this view of the subject corroborates the principle already alluded to, that it is owing to the development of wings that the *Phylota*, or winged insects, are necessarily subjected to a more complete and astonishing series of transformations, than the other annulose animals, in which the changes (to which, in fact, in a greater or less degree, all animals are subject) consist in a periodical casting off of the outer envelope. It is true, that in a few insects, which are evident exceptions to the general rules, this same mode of moulting takes place; and it is also to be observed, that during a certain and early period of their existence the same principle exists throughout the winged tribes of insects which, in such cases, represent in their imperfect state the perfect state of the other *Annulosa*. We have already said, that, owing to the external envelope of annulose animals constituting their skeleton, and offering from its stronger consistence a complete obstacle to the increase in size of the enclosed animal, it was necessary that this skeleton should, from time to time, be cast; we have, however, still to inquire, how the animal which throws off so important a portion of its organs as its skeleton, can exist, or in what manner a new skeleton is formed. Swammerdam, in his really wonderful series of observations, discovered, in his endeavours to prove that all insects were produced from eggs, and that the caterpillar was but an immature butterfly, that, shortly previous to changing to a chrysalis, the various parts of the butterfly were found distinctly encased beneath the skin of the caterpillar. And therefore he has raised the theory which has been generally adopted by subsequent authors, that every caterpillar, at its first exclusion, contains within itself the germe of the future butterfly, and of all its envelopes, which, successively presenting themselves, are thrown off, till it attains its perfect winged state. This theory has, however, been completely opposed by Dr. Herold, a distinguished microscopic observer, who, from a most elaborate, indeed, we may affirm, the most elaborate investigation of the kind, hitherto made, upon the cabbage-butterfly in its various states, has arrived at the contrary conclusion—that the successive skins of the caterpillar, the pupa case, &c., do not

pre-exist as germs, but are formed successively from the *rete mucosum*, which itself is formed anew upon every change of skin; these formations being attributable to the action of a power which he terms the *vis formatrix*.

Against the latter theory, Messrs. Kirby and Spence have raised various objections, none of which appear to the author of this article to be of sufficient weight to overthrow it in favour of the old theory of Swammerdam. The first of these objections is, that Dr. Herold employs the high-sounding term, *vis formatrix*, to conceal his own ignorance of causes, when endeavouring to penetrate within the sanctum sanctorum, which is not permitted to vain man to enter—a plan adopted in all ages, and instanced in the adoption of such words as *Plastic Nature*, *Epigenesis*, *Panspermia*, *Idea seminalis*, *Nisus formativus*, &c. It is evident from these observations, that these authors would endeavour to fix upon Dr. Herold a charge of infidelity, in supposing that the structure of an insect possessed of itself a power to mould itself according to its own formative will and power. And this is evident, because in a subsequent page they adduce the fact, with which every physiologist is acquainted, that the developments and acquisition of new parts and organs, by insects undergoing metamorphoses, have taken place according to a *law*, which regulates their numbers, kinds, and times, since the first creation. But surely they are not authorised by Dr. Herold's views and statements, in wielding against him this powerful (if maintainable) argument, since it must be evident, that by the term *vis formatrix*, Dr. Herold meant not to imply any power independent of the Creator, but simply that principle of development which, under the guidance of an Almighty hand, is constantly in operation, not only in insects, but in every other branch of the creation\*. It would be as unjust to assert, if a man, whose finger had just healed from a wound, and who should thereupon say that he had gained a fresh layer of skin by the action of his flesh, that he was an atheist. But in the next place, Messrs. Kirby and Spence do not deny the facts stated by Dr. Herold, that the organs of the butterfly are not discernible in the larva, but gradually become visible, as the caterpillar throws off its successive coverings. They assert, indeed, that they can easily comprehend that pre-existent germs, by the constant secretion of new matter, in a proper state, may be gradually developed; but find it impossible to conceive how, by the action of second causes, without the intervention of the first cause, the *butterfly should be formed in the caterpillar*, unless it pre-exists there as a germe or fœtus. The question is not, however, whether the butterfly be or be not inclosed as a fœtus within the caterpillar; but whether, as Swammerdam evidently intended, the various skins of the caterpillar, &c. existed as distinct and visible germs within the newly-hatched caterpillar; and this Messrs. Kirby and Spence endeavour to support, by the argument which they adduce from Bonnet, that "organs that have no existence as to us, exist as they respect the embryo, and perform their essential functions; the term of their becoming visible, is that which has

been erroneously mistaken for the period of their existence."

The question, therefore, now assumes a new form. It is not, as between Swammerdam (contending that the successive skins of the caterpillar exist as distinct and visible germs in the newly born caterpillar), and Dr. Herold (asserting that these skins are successively produced from the *rete mucosum*), but simply whether we are to consider with Kirby and Spence, that these germs are pre-existent, though not perceivable even by the application of the most powerful microscope, but which subsequently, "by the constant accretion of new matter in a proper state, are gradually developed;" or with Dr. Herold, that they do not pre-exist as germs, but are successively formed from the *rete mucosum*. Having, however, divested the arguments of the latter from the charge of atheism which has been attempted to be forced upon them, we really are not prepared to consider that there are no grounds for the adoption of the latter in preference to the former. It is true that Dr. Herold discovered the organs of sex in the newly excluded larva; but these and other organs of the perfect butterfly, are those which, from their very nature, must be regarded as requiring the greatest and most gradual degrees of development; but the case is quite different with such temporary organs as the skins of the caterpillar: but let us look to facts,—Messrs. Kirby and Spence are unable to adduce any in support of the existence of invisible germs, but according to Dr. Herold, there is not the least trace in the young larva of the new skin, but this first originates towards the end of the first period of the caterpillar's life, a few days only before the old one is stripped off. It is then observed that the mucous and muscular layers of the skin separate all round, from the epidermis, and then clothe themselves upon the superior surface with a new epidermis. The development of this new external skin occupies two or three days, during which the caterpillar appears sickly, and takes but little nourishment; the old skin then splits longitudinally along the back, and the caterpillar emancipates itself from its old envelope by drawing out the body. The epidermis, all the external visible organs, and even the mandibles and palpi, remain attached to the old skin. This moulting is repeated several times.

Various physiologists, and especially Dr. Virey, have endeavoured to trace an analogy between the transformations of insects and the development of some of the higher animals; attributing, as Mr. Mac Leay observes in his *Horæ Entomologicæ*, the metamorphoses of insects to the shedding of an envelope analogous to that which contains the fœtus of the more perfect vertebrata. And as every embryo, whether animal or vegetable, is inclosed in a tunic more or less solid (its chorion), so proceeding with the analogy, they conceive there must be some condition for every animal, similar to the state of the fœtus of the more perfect animals, when surrounded by the amnios of this state, and which in the hexapod insects, they hold to be the larva, according to which the true birth of the animal will be its exclusion from the pupa case. This argument seems to have been derived from an observation of Reaumur—namely, that the larva of insects ought to be regarded as an egg of an extraordinary kind, endowed with organs of locomotion and nutrition; and that this analogy is also retained during the period of the insect's existence in

\* It is rather remarkable, that Messrs. Kirby and Spence, after having thus endeavoured to brand Dr. Herold as an atheist, should have expressed a supposition, that the skins of serpents are formed under the old skin, from the *rete mucosum*, (Vol. III. p. 191.) The *vis formatrix* of Dr. Herold, is of no higher rank than the power implied in this expression.

the chrysalis state. When we consider, however, that many species of insects are active in the pupa state, and that on their exclusion therefrom they have acquired their full size, and are fitted for the reproduction of their species, we must admit that the former view of the subject is scarcely maintainable; and that the larva state, which is especially that in which the digestive system predominates, and the greatest supply of food is taken, is more strictly analogous to the period of infancy of the higher animals.

We are now to examine,

Section 2.—*The peculiarities exhibited by insects in their passage to the perfect state.* Perhaps none of the phenomena of natural history have attracted a greater share of the attention of mankind in all ages, than those exhibited by insects in their passage to the perfect state. It is perfectly consistent with that innate propensity of the human mind towards the marvellous, that the change of a caterpillar into a butterfly should have been considered by the ancients as a true metamorphosis, in no manner reconcilable with the ordinary process of nature. If this were indeed the case in the darker days of zoological knowledge, when the true nature of these changes was not understood, it is equally certain that the subject has lost none of its interest, although, owing to the admirable researches of Libavius and Redi, Malpighi and Swammerdam, Reaumur and De Geer, all of the marvellous has been removed, and a series of gradual developments exposed far exceeding in peculiarity those exhibited in any of the other tribes of animals.

But it is not alone in elucidating the nature of the changes, by means of which a caterpillar becomes a butterfly, that the researches of these authors are most valuable; since this discovery naturally led to the equally important truth that the caterpillar is produced from a creature which has at one period of its existence resembled itself; and which, having arrived at its perfect state, and been impregnated, has perpetuated its species by the deposition of eggs, which, when hatched, produce small voracious animals of variable forms, ordinarily termed caterpillars, grubs, or maggots, and systematically larvæ (plural of the Latin word larva), liable to a series of moultings, varying in number. To this state in the majority of insects, succeeds a quiescent period, during which the appearance of the creature is completely altered. The insect in this state is termed a chrysalis, or aurelia, and more generally and technically a pupa (plural, pupæ). After remaining in this state a certain period, the insect again throws off its covering, and appears in its perfect form. It is now termed a beetle, butterfly, bee, &c., according to its kind, but technically and generally the term imago is applied, to designate the adult state of all insects. These terms, larva, pupa and imago, were employed by Linnæus, whose nomenclature was often fanciful, although generally applicable; the first, in allusion to the *larvated*, or *masked* appearance of the insect whilst a larva; the second, from the resemblance of the insect, during the pupa state, to the mummy-like appearance of children wrapt up in swaddling clothes; and the third, because having laid aside its mask, and cast off its swaddling clothes, it is now in its perfect state, and has become a true representation or image of its species. Hence the four stages of an insect's existence are the egg, larva, pupa, and imago.

It is true, however, that, as we have already

shown in our articles APHIDES and BLOWFLY, the eggs, but very rarely, are hatched within the body of the parent fly, and deposited as larvæ; and that, in the *Hippoboscidae*, the larva even undergoes its change to the pupa state previous to being deposited by the parent; but still these insects have originated from eggs; and it is also true, that in some groups the insect in the pupa state is active, and differs only from the larva in having small tubercular rudiments of wings upon the back (as in the orders *Hemiptera* and *Orthoptera*); and in the apterous individuals of these orders it is next to impossible to assert whether an individual be in the larva, pupa, or imago state. These are, however, but exceptions to the general rule, and do not warrant the opinion maintained in an ingenious paper published by Mr. Newman in the *Entomological Magazine*, to which we would refer the reader; namely, that insects have but three stages of existence, the fetal, the adolescent, and the adult, inasmuch as in the majority of insects, the last is preceded by a distinct but variable state, which we have above noticed as that of the pupa. In like manner, we see no sufficient grounds for rejecting the terms larva and pupa, and employing such terms as infancy and adolescence in their stead. Indeed, the setting aside of words employed in a technical sense, and universally understood, merely because they may happen to be in a foreign tongue, or may, even in their origin, have been somewhat fanciful, appears to us to savour somewhat of affectation, or even something worse than this, when the perfectly quiescent and apparently lifeless state of an insect is regarded as analogous to the adolescence of the higher animals.

Our present inquiry, therefore, resolves itself into four distinct heads—namely, the egg, larva, pupa, and imago.

1. *The Egg.*—We have already seen in the present article, as well as in various others of our entomological articles, that there is no ground for the popular idea that any kind of insect is produced otherwise than from eggs deposited by a parent. The first branch of our inquiry will therefore be devoted to the situation in which the eggs of insects are deposited, and the extraordinary instinct exhibited by the female in this operation, and which has been attributed to the influence of maternal affection. As, however, it happens that, in the great majority of instances, the female dies immediately after depositing, and long previous to the hatching of, her eggs; and as, moreover, it is erroneous to attribute such feelings as love or affection to animals so low in the scale of existence as insects, we would refer these proceedings to the operation of that indefinable influence which is ordinarily termed instinct. That this is a correct view of the matter, must be evident from a perusal of the details which we have furnished of the proceedings of the hive-bee and of the ants; where we have seen that insects incapable of reproduction (neuters) are equally active in preparing nests, &c., as the real parent. This branch, therefore, of our inquiry, ought perhaps more correctly to come into our physiological view of insects, although it can hardly be said to be out of place here.

Insects, as regards the situations in which their eggs are deposited, may be divided into two classes; those which, with much labour, form a residence, and lay up a store of food for their progeny; and those which simply place them in situations where the young, when hatched, will be certain to find a due supply of food.

Of the former, the highest place must be accorded to those social insects which build nests of the most beautiful construction, serving not only for the education of their young (which are produced from eggs placed in separate cells), but also for the habitation of the entire community at large. We must refer to our articles upon the BEE (Hive-Bee), HUMBLE BEE, HORNET, WASPS, ANTS, and FORMICIDÆ, WHITE ANTS, TERMITIDÆ, &c., for many details which it would be useless to repeat. We are next to notice the sand-wasps, and many solitary species of wild bees and wasps, which construct their nests with great labour in the sand or in rotten wood, forming a succession of cells generally of an oval or rounded form, in which they deposit a supply of food either of pollen, paste, or other insects, sufficient for the nourishment of the larva when hatched from the egg, which is placed in the cell with this supply. We have already given instances of this mode of proceeding in the articles CERCERIS, FOSSORES, CERATINA, HALICTUS, &c. Here also may be ranked the dung-rolling and dung-boring beetles, whose history we have given under the articles GEOTRUPES and GYMNOPLURUS, as well as the burying-beetles (*Necrophagus*), whose exploits in burying small dead animals, in which they deposit their eggs, are not less indicative of a high degree of instinctive powers. The *Cicadæ* likewise, as well as the saw-flies, may also here be noticed, since the care with which the parent constructs a burrow in the stems of plants, for the reception of her eggs, by means of a most admirably constructed apparatus, is equally remarkable, although the larva, as soon as hatched, is compelled to seek elsewhere for its food, namely, the leaves on the adjoining twigs. But the instinct which is exhibited in the selection of appropriate situations for the eggs, and where the larva, when hatched, will find a supply of food, without the same being laid up in store by the parent fly, is found to be possessed by the greatest number of insects. Many species of larvæ will feed only upon one particular species of plant; and the parent fly, in its perfect state, takes no other food than a little honey from every flower which may be in bloom at the time; still it is only upon that particular plant which suits the taste of her progeny that she deposits her eggs. Here are to be ranked many of the tribes of lepidopterous insects (Butterflies and Moths). Many species of moths, as well as beetles, reside in the larva state under the bark of trees; the females, therefore, by means of a long and jointed ovipositor, are enabled to place their eggs at the bottom of the crevices in the external bark. In like manner, the carrion flies deposit their eggs upon carrion; the flesh-flies upon flesh; the flies whose larvæ feed upon plant-lice, in the midst of the plant-lice; and some species of these flies (*Hemerobius*) render the security of their young doubly secure, by placing their eggs out of danger at the extremity of long and slender foot-stalks (fig. 9). In like manner, the boat of eggs formed by the gnat (see our article CULICIDÆ), and the egg-pouch of the *Hydrous*, are alike deserving of notice. But it is amongst the parasitic insects that this species of instinct appears most fully developed. Of this we have already given numerous instances in our articles upon the CUCKOO-BEES, CHRYSIDIDÆ, CHALCIDIDÆ, and especially ICHNEUMONIDÆ; whilst the proceedings of the bot-flies, and the instinct whereby, as in the *Gasterophilus equi*, a particular spot upon the body of an animal is selected for the reception of the egg,

NAT. HIST.—VOL. II.

is most remarkable. It would, however, be an almost endless task to detail the various modes adopted by insects in order to deposit their eggs in such situations that their progeny may be sure of meeting with an ample supply of food.

If the instinct exhibited by the parent fly be worthy of observation, the number of eggs which she deposits is not less interesting. Thus the queen bee produces from 40,000 to 50,000 eggs in the course of a year, and supposing a swarm to contain 32,256 individuals, and three swarms to take place in the season, the population of a hive would in a single year amount to nearly 100,000 bees; and the *Aleyrodes proletella*, a little homopterous insect, may give birth in a year to more than 200,000 young. A species of moth, according to Lyonnet, produces in the third generation more than a million of young; and the *Aphis*, observed by Reaumur and Bonnet, produced at the fifth generation 5,904,900,000 individuals, and there may be not less than twenty generations in the course of a year. The female white ant, whose enormously distended body causes her to exceed her companions many hundred times in size, deposits sixty eggs in a minute, which is at the rate of 211,449,600 in the course of a year. Other insects are, however, less prolific. The silkworm produces only from 400 to 500 eggs, the caddice flies less than 100; the burying beetles about thirty; and the horsefly (*Hippobosca equina*) can only be said to deposit a single egg.

The eggs of insects are generally of an oval form (fig. 1, oval-spotted egg of the fox-moth), the outer covering being sufficiently rigid to resist ordinary external impressions; others are, however, soft and pliant. In some species they are globose, as in many lepidoptera (fig. 2, globular-banded egg of the vapourer-moth); or conical, as in the large white cabbage butterfly (fig. 3); cylindrical, pear-shaped, barrel-shaped, &c. They are for the most part smooth; but many are very beautiful, ornamented with symmetrical ridges (figs. 3 and 4, egg of the tortoise-shell butterfly), canals, dots, &c., giving them as Reaumur observed, the appearance of embossed buttons. There are numerous other varieties in the form of eggs, and some are furnished with appendages for peculiar purposes. Thus the egg of the dung-fly (*Scatophaga putris*, fig. 5) has two oblique props at one end to prevent it sinking too deep in the matter upon which it is deposited; whilst those of the water scorpion (*Nepa cinerea*, fig. 10) are furnished with a coronet of spines forming a receptacle for the egg, which is deposited immediately afterwards.

The colour of insects' eggs varies very considerably, although white, yellow, and green are the more prevalent tints; orange, red, brown, and black, with all the intermediate shades, are to be found, as well as blue; and others are banded with pale circles, and that of the pine lappet moths is blue with three brown zones. The colours of eggs are, however, subject to change as the inclosed larva approaches the period of its escape, this being owing chiefly to the change of

G G G

colour undergone by the latter being visible through the slender coating of the egg.

In many species the eggs are deposited singly; in others, however, they are discharged *en masse*, of which latter, the most remarkable instance occurs in the cock roaches (*Blatta*), of which we have already given an account. Others again arrange them symmetrically (as in the cylindrical pointed eggs of the *Sembris lutea*, fig. 6), and others enclose them in a mass of gluten, especially those species which inhabit the water in the larva state; many species employ a gummy matter to attach them firmly to the substances on which they are placed; whilst some (as the yellow-tail moth, *Arctia chrysorrhæa*) wrap them in a coating of down (fig. 7), which they pull off their own bodies by the assistance of an apparatus fitted for that purpose; and the lackey moth (*Lasiocampa Neutria*) deposits her eggs in a spiral coil round the stems of fruit-trees (fig. 8).

The period which elapses between the deposition of the egg and the birth of the larva depends upon the temperature of the atmosphere, as well as upon the species of insect. Thus, whilst the early laid eggs of the tortoise-shell butterfly hatch in a few days, those which are not laid till autumn will not produce caterpillars until spring. The eggs of the meatfly hatch in a very few days, or even hours; eight days are required by the eggs of the painted lady butterfly; whilst the caterpillars of the machaon butterfly are not hatched under a month. It is, however, a general rule, that those eggs which are deposited in the autumn are not hatched until the following spring.

The investigation of the development of the grub whilst inclosed within the egg is attended with so much difficulty, owing to the minuteness of the objects, that hitherto but little progress has been made in this branch of the subject. Dr. Herold, however, whose admirable microscopic observations we have already noticed, has taken it up; and the first part of his magnificent work entitled "*Disquisitiones Animalium Vertebris carentibus in ovo Formatione*," has recently appeared, and will tend to throw much light upon this intricate subject. One peculiarity ought not to be omitted relative to this part of our subject, namely, that the eggs of the sawflies, gallflies, and ants, increase very considerably in their size, and alter in form previous to the exclusion of the larva, and which is doubtless owing to the membranous covering of the egg and to the growth of the inclosed larvæ. In general, the embryo caterpillar is observed coiled up within the egg, the head being brought into contact with the tail.

We have said that the majority of insects die previous to the birth of their progeny, but this is not the case with the whole. Thus De Geer ascertained that a large species of field-bug (*Pentatoma grisea*) survives this event, and that she leads her brood about, consisting of from thirty to forty young ones, in the same way as a hen does her chickens. Some-

what similar observations have been made upon the common earwig by De Geer, as well as by the author of "*Insect Transformations*," who has published the following interesting notice in the Penny Magazine: "About the end of March I found an earwig brooding over her eggs in a small cell scooped out in a garden border, and in order to observe her proceedings, I removed the eggs into my study, placing them upon fresh earth under a bell-glass. The careful mother soon scooped out a fresh cell, and collected the scattered eggs with great care to the little nest, placing herself over them, not so much, as it afterwards appeared, to keep them warm, as to prevent the too rapid evaporation of their moisture. When the earth began to dry up she dug the cell gradually deeper, till at length she got almost out of view; and whenever the interior became too dry, she withdrew the eggs from the cell altogether, and placed them round the rim of the glass, where some of the evaporated moisture had condensed: upon observing this, I dropped some water into the abandoned cell, and the mother soon afterwards replaced her eggs there. When the water which had dropped had nearly evaporated, I moistened the outside of the earth opposite the bottom of the cell, and the mother perceiving this, actually dug a gallery right through to the spot where she found the best supply of moisture. Having neglected to moisten the earth for some days, it again became dry, and there was none even round the rim of the glass as before. Under these circumstances, the mother earwig found a little remaining moisture quite under the clod of earth, upon the board of the mantel-piece, and thither she forthwith carried her eggs. The subsequent proceedings were not less interesting; for though I carefully moistened the earth every day, she regularly changed the situation of the eggs morning and evening, placing them in the original cell at night, and on the board under the clod during the day, as if she understood the evaporation to be so great when the sun was up, that her eggs might be left too dry before night. I regret to add, that during my absence the glass had been moved and the mother escaped, having carried away all her eggs but one or two, which soon shrivelled up." De Geer was more fortunate, and as we have ourselves repeatedly observed, noticed the care of the female in defending her young when hatched.

There are other insects whose attention is devoted to the care of the eggs and the education of the young, especially in the social species. When the period is arrived for the hatching of the egg, the inclosed larva bursts through the envelope, either by main force or by gnawing through it with its jaws. Sometimes, however, one end of the egg is provided with a sort of cap, which is easily pushed open.

*The Larva.*—The insect has now arrived at an active state of existence; it is now that it is destined, in a more especial manner, to grow and to eat. It is to this state that the ordinary terms caterpillar, grub, and maggot are generally applied in a manner so indefinitely, that it is impossible, with any pretension to correctness, to assign these terms to any precise divisions of insects. In general, insects at this period of their lives appear in the form of a cylindrical ringed and fleshy worm, provided generally with a distinct head and six scaly legs attached to the anterior part of the body. The head, however, in some species is not distinct, and the legs are sometimes

wanting; whilst in others the terminal segments are furnished with membranous (false or pro-)legs. In other species, however (the number of which is but comparatively small), the insect nearly resembles its parents, being, however, destitute of wings. This variation naturally introduces two principal divisions amongst insects, the former being said to have a complete metamorphosis, and the latter an incomplete one; but as these terms have also been employed by Linnæus and Fabricius in a more restricted and totally different sense, and as they have been applied to designate the entire metamorphosis, instead of simply indicating the formation of the larva, we prefer dividing insects, from a consideration of their larvæ, into two divisions, which may thence be named *Heteromorpha* and *Homomorpha*.

In all this diversity, however, there is still a general prevailing uniformity of structure, which, under various modifications of form, preserves a tendency towards one typical organisation. This typicality in larvæ consists in having the body ordinarily composed of thirteen segments, which are for the most part of an equal size, although when arrived at maturity, some of these segments become obsolete, being converted into internal organs, or are greatly altered as regards the extent of their individual development. Here the entire object of the animal's existence consists in its capability of feeding; consequently, owing to the formation of the internal digestive organs, the body maintains throughout its various segments a general conformity, none requiring an extra development for the support of organs fitted for other purposes. When, however, the insect has arrived at the perfect state, its objects are completely altered, it has now to seek its mate; it is therefore provided with wings, which requiring support from the segments to which they are attached, cause these segments to be necessarily developed in an extraordinary degree; the other adjacent segments being losers: the insect has also now to perform the great object of its existence, namely, the continuing of its kind, and therefore the organs of generation become organs of especial importance, and we accordingly find other portions of the body sacrificed for their development.

The thirteen segments which compose the body of the larva bear the following relation to the distribution of the segments in the imago. The first segment or head of the larva becomes the head of the imago; the three following segments compose the thorax, and the remainder become the abdomen in the perfect insect. Dr. Ratzeburg has, indeed, lately published a memoir, endeavouring to prove that the two first segments of the larva of the aculeate *Hymenoptera* become the head of the imago; but the observations of this author, as we have proved more than once, are incorrect, and founded upon very unphilosophical views.

In the *Homomorphous* division, the larvæ greatly resemble the perfect insect, differing chiefly in being entirely destitute of any appearance of the organs of flight. The second segment of the body also does not exhibit the shield-like scutellum which is found in the imago in that situation; here belong the various tribes of locusts, grasshoppers, and crickets (fig. 11, larva of the cricket), bugs (fig. 12, larva of a *Pentatoma*), tree and frog-hoppers, cockroaches, preying mantes, &c., constituting the orders, *Orthoptera*, *Hemiptera*, and *Homoptera*, as well as some portions the order *Neuroptera*. Some of these insects are,

however, remarkable for being destitute of wings in the perfect state, and a difficulty thence arises of distinguishing the larvæ from the subsequent states. The variation in their size, and the constant absence of ocelli, as well as a somewhat less perfectly developed organisation of the antennæ; these, and some other parts of their structure, may serve to distinguish them. From analogy with the higher animals, we might, perhaps, be induced to consider that these insects which maintain a constant activity throughout their existence, are much higher in the scale of nature than those species which, like the butterfly, are subject to so long a period of death-like repose.

In the *Heteromorphous* division the larva is totally unlike the perfect insect, being generally more or less vermiform, and, with the exception of the head, of a leathery-like texture. Here belong the tribes of beetles, butterflies, moths, bees, and most other four and two-winged flies, as well as the flea. There are, however, various modifications of form in respect to the head and eggs of the larvæ of those insects, so that it may, perhaps, be advisable to give a sketch of their distribution, proceeding from the more fully to the less perfectly developed species.

A. *Larvæ capitata*, or those having a distinct head, sub-divisible into

1. *Hyperhexapoda*, or those having six legs, and a variable number of membranous prolegs.

The larvæ of butterflies (fig. 14, larva of Camberwell beauty butterfly), moths and saw-flies (fig. 13, larva of *Cimber lutea*).

2. *Hexapoda*, or those having six scaly legs, but being destitute of prolegs. The larvæ of many *Coleoptera* (fig. 15, larva of *Trichius nobilis*), and some *Neuroptera*.

3. *Apoda*, or those destitute of legs and prolegs. Many *Coleoptera*, *Hymenoptera* (fig. 16, larva of wild bee), gnats and tipulæ (fig. 18, larva of *Tipula*), and the flea (fig. 17, larva).

B. *Larvæ ecapitata*, or those without a distinct scaly head, including the majority of dipterous insects (fig. 19, larva of the flesh fly), some few of which are furnished with membranous tubercles serving as prolegs.

The head, in the generality of larvæ, is covered with a corneous case, often divided by an impressed line running down the middle of the face, into two

lateral lobes; its form is more or less rounded, but it often assumes a triangular or heart-shape; occasionally, as in the caterpillars of some butterflies, the two lobes are terminated by spines or tubercles. There are other variations in the appendages by which this part of the body is distinguished. In the second section above described, the head is generally retractile, membranous, and variable in form, and destitute of eyes and antennæ, as well as of the ordinary parts of the mouth, which appears only to consist of a pair of hooks, or bristles, which are incapable of either cutting or grinding; the insect employs them not only to pierce the soft matters, upon the juice of which it feeds, but also as claws whilst engaged in locomotion.

The head of larvæ is generally provided with a pair of short rudimental antennæ, eyes and organs of the mouth.

The antennæ (fig. 20, b) are placed near the base of the mandibles; they are for the most part totally unlike the antennæ of the perfect insect, although in the homomorphous section they are very similar in this respect, although shorter, and composed of fewer joints. These organs are, however, in general very short, and composed of three or four joints; and in many groups they are entirely wanting in the larva state.

The eyes of larvæ are not, like those of the perfect insect, formed of an innumerable series of hexagonal lenses, but consist of a small number of simple granular tubercles, placed at the sides of the head, in the same situation that the eyes of the future insect are to be developed; they are, therefore, more analogous to the simple eyelets of many insects which we shall subsequently describe under the name of ocelli; many larvæ are, however, entirely destitute of them. Their numbers, when present, seldom exceed six on each side, which is the number possessed by the caterpillars of butterflies (fig. 20, a). The larvæ of the dragon flies have eyes somewhat resembling those of the perfect insect.

The mouth of the majority of larvæ consists, like the mouth of the perfect insect, of an upper lip (fig. 20, c), a pair of horny jaws (fig. 20, d), a second or lower pair of jaws of less firm consistence (fig. 21, e), furnished with an articulated palpus (fig. 21, f), and a lower lip (fig. 21, g), furnished also with a pair of articulated palpi (fig. 21, h, i). Here, however, we have to remark that the structure of the mouth of the larva will, by no means, lead us to a correct idea of the mouth of the imago; thus the jaws of the caterpillars of butterflies are as robust, and not very unlike those of the larvæ of beetles; but the mouth of the former consists of a slender spiral and tubular apparatus for sucking up honey, whilst that of the latter retains much of the general appearance of the mouth of the larva. There are some peculiarities in the

structure of various organs of the mouth, which it may be interesting to notice. Thus the jaws of the antlion fly, and of the predaceous water beetles, are very long, slender, curved, and sickle-shaped, having a small longitudinal aperture near the extremity, which communicates with an internal canal, through which the juices of the prey of the insect pass. Another remarkable peculiarity exists in the elongated elbowed structure of the lower lip of the larvæ of the *libellulidæ* (dragon-flies), which we have already described, and which is employed like an arm furnished with claws for seizing their prey. Again, in those larvæ which spin for themselves silken cocoons, in which they undergo their transformations, the lower lip is furnished at its extremity with a minute and slender organ (fig. 21, i), which Kirby and Spence have aptly termed the spinneret (*fusulus*), composed of several longitudinal slips alternately corneous and membranous, whereby the insect has the means of contracting the tube, which terminates in a single orifice, and through which the insect emits its silken threads, which, although elaborated in two distinct silk tubes, unite previous to their emission from the orifice of the tube. Some larvæ, indeed, spin a silken thread for the formation of cocoons from a distinct apparatus at the extremity of the body.

We now pass to the description of the other segments of the body of larvæ, and the organs of motion, and other appendages with which they are provided. Generally speaking, these segments, which are typically twelve in number, are of a cylindrical and elongated form; but various modifications occur, some larvæ being flattened, others oval, some short and thick, others having the segments very irregular, warty, spinose, or hirsute. The three anterior segments are, however, ordinarily distinguished by each having on its inferior surface a pair of short scaly legs, composed of four or five joints, which are analogous to those of which the legs of the perfect insect are composed, and generally terminated by a small claw (fig. 22). In many larvæ, as we have indicated in the table given above, these are the only legs with which the insect is furnished, although it rarely occurs that these are wanting, the organs of motion being the merely rudimental prolegs. These prolegs are thick, and of a membranous construction, so that, unlike the true articulated legs which are capable of motion only at the articulations of the joints these are completely flexible. These legs are exclusively adapted to the insect whilst it remains in the larva state, there being nothing at all analogous to them on their arrival at the perfect state. These legs are furnished at the extremity with a multitude of minute bent hooks, which are employed by the larva in retaining its situation, upon whatever substance it may happen to be placed, with very great firmness (fig. 23 and 24). These prolegs are very variable both in their structure and situation, as also in their number varying from two to eighteen. These

variations afford grounds for classifications of the larvæ, but which it would be tedious to detail without entering more fully into minute particulars than our space will allow. In like manner the various horns, spines, and protuberances must be passed over in silence, especially as we have already in our article *CATERPILLAR*, and upon various other occasions, noticed any remarkable variations which may occur in those respects. It remains, however, to be noticed, that the terminal segment of the body is often very different from the preceding in its form, and that its underside in some hexapod larvæ is furnished with a retractile tubercle, which the insect sometimes employs as a seventh leg.

In addition to the organs above described, are to be noticed the spiracles, or apertures by which the larvæ take in a supply of air. These spiracles are not, as in the higher animals, situated in the head, but are arranged in a series on each side of the body, opening into two longitudinal tubular internal vessels called tracheæ, from which an immense number of ramifications diverge to every part of the body of the insect. These spiracles are placed in the first, fourth, and following segments (except the last), and consist of a small elongated opening surrounded by a callous margin (fig. 25 represents a spiracle open, and 26 a closed spiracle). In aquatic larvæ, however, a variation in the organization of the animal necessarily takes place, as it is not exposed to the ordinary action of the air. We have seen already in our article *DYTICIDÆ* and *DRAGON-FLY*, how this is effected in these insects; but in other aquatic larvæ, as in the *EPHEMERÆ*, the sides of the body are furnished with elongated flattened plates, through which a slender air tube meanders, and which communicates with the longitudinal air tubes above-mentioned. (fig. 32.) Other variations occur in the larvæ of the gnats (*Culicidæ*) and midges (*Chironomus*), which we have already described. But the most curious variation which occurs in this respect, is found in the very common larvæ of the *Helophiæus pendulus*, which has been termed the rat-tailed grub, from the peculiar formation of the extremity of the body, which is very slender and elongated, enclosing a second still more slender air tube, which is capable of being protruded, so as to be pushed to twelve times the entire length of the body. As the insect lives in mud, this structure is eminently serviceable in enabling it to obtain a due supply of air.

There are, however, some considerations resulting from the variations in the form of the larvæ of insects which ought not to be passed over without notice, inasmuch as the subject is one of great interest, hitherto but little cultivated, and one of much importance as regards the classification of the annulose sub-kingdom. We have already observed that the immature state of insects typified the perfect forms of those particular grades through which the winged type may be supposed to have passed in its progress to maturity. Without arriving at this theory as stated above, Mr. MacLeay, in his *Horæ Entomologicæ*, and Messrs. Kirby and Spence, have given a series of analogies exhibited by the larvæ of insects with other annulose groups; the former contending that it is only by the assistance of such analogies that the real mode of distribution (by which every variation shall have its due weight appropriated to it), and the consequent discovery of the natural system, can be attained; thus the larvæ of the cockchafer, and other lamellicorn beetles, represent a full-grown *Iulus* in its peculiar

mode of rolling itself into a coil on one side; and the same analogy is exhibited by the larvæ of the sawflies. It would lead us too far to enter more at length into these views which, however, it would have been improper to have entirely overlooked.

We have said that it is during the larva state that the chief supply of nutriment is taken by the larva. It will be proper, therefore, that we should enter into a few particulars relative to the voracity of insects at this period of their existence, and which, in proportion to their size, far exceeds that which is exhibited by any of the larger animals. Thus Redi discovered that the larvæ of the flesh fly had become, in the space of twenty-four hours, at least two hundred times heavier than before. And the Count Dandolo gives the following as the result of the most exact calculations made from the observations of the cultivators of silk, who know the exact weight of the leaves devoured by the caterpillars; 1609½ pounds weight of leaves being consumed by the progeny raised from an ounce weight of eggs.

First age,	6 lbs. of sorted leaves, 1½ lbs. refuse	
Second age,	18	3
Third age,	60	9
Fourth age,	180	27
Fifth age,	1098	102
		105 allowed for evaporation
	1362	+
		247½ = 1609½ lbs.
Deduct further allowance for litter, unclean leaves, &c.	155½	
		1206½ lbs. actually devoured.

But it is to be observed, however, that the stomachs of these insects, like that of the horse (see *HORSE*), does not possess the power of dissolving these leaves in the most perfect manner, but only of extracting a juice from them. Indeed this very circumstance is assigned by John Hunter (*Observations on the Animal Economy*, page 221, quoted by Kirby and Spence) as the probable proximate cause for the voracity of herbivorous larvæ. And hence, of the 1206½ pounds of leaves actually devoured, 745 pounds are deposited as excrement in an indigested state. Hence it is evident that in comparison with the stomach of the perfect insect, in which state but very little food is in general taken, and in some cases the insect is even totally destitute of a mouth, the stomach of the caterpillar, and its apparatus for taking its food, must be fully developed; and this is found to be the case, the stomach occupying a considerable portion of its interior, and the organs of the mouth being very robust. The caterpillar of the goat moth is three years in arriving at its full size, when it is 72,000 times heavier than when newly hatched; and a silkworm, weighing when first hatched 1-100th part of a grain, consumes in thirty days about 60,000 times its primitive weight.

These particulars may suffice for the voracious powers of individual insects. It is when they have been produced in considerable numbers together that these powers are rendered more widely perceptible; and in fact become highly prejudicial, as we have already endeavoured to shew in the early part of this ARTICLE. An instance or two may not, however, be here out of place. Of these, the first we shall mention is the salt-marsh caterpillar of North America, of which an interesting account has been published

by Dr. T. W. Harris, in the Massachusetts's Agricultural Repository. This insect is the caterpillar of a moth allied to our ermine spot moths, being the *Arctia acria* of Fabricius. It is very hairy, somewhat like the caterpillar of the garden tyger-moth, and is endued with a great degree of vitality, for long immersion in water does not destroy life. Being often exposed to that element, they seem provided with the power of enduring its approaches. They feed twice in the day, about ten o'clock in the morning, and four in the afternoon. If overtaken by the tide while feeding, they mount to the top of the grass, and then, if obliged to relinquish their hold, contracting themselves into a circular form, they commit themselves to the water. By this means they are washed to the borders of the marsh, where they are left by the wash of the sea in heaps, but alive, and in a short time ready to re-commence their depredations upon the meadows. The hair upon their bodies seems to possess a repelling power, which secures the spiracles from the admission or access of the water, for were this to be the case, the insect would be drowned. Their most favourite food is the onion grass, which is very succulent; but they are not fastidious, and eat with avidity 'fox' and 'bottom grass,' and even 'thatch' and 'sedge.' By the first of August these caterpillars have attained their greatest size; they now become very voracious, and continue eating all the day and night without intermission, by which means the hay crops are greatly detrimented. Soon they leave the meadows aggregated in great numbers, and commence their wandering state, or 'begin to run,' as is the phrase, devouring every thing in their progress. Corn-fields, gardens, and even the coarse and rank produce of road sides, afford them temporary nourishment, until they have found a place of security against the tide and weather. Another moth, belonging to the same group, of whose proceedings an account was published in 1782, by Mr. W. Curtis, under the name of the brown-tail moth, *Porthesia auriflua*, is occasionally not less numerous nor injurious in our own country. In the year above mentioned, so vast were their numbers, that the trees were despoiled of their foliage; and it was feared that they would extirpate the growing corn and grass, and starve the cattle to death in the fields. They were regarded as the harbingers of the plague, and prayers were ordered to be read in all the churches, to avert the supposed impending calamity. In France, also, the same, or nearly-allied species has so frequently appeared in such prodigious numbers, to the defoliation of the forests, that the legislature have promulgated several ordinances for their destruction.

The colours of larvæ are very variable; indeed it would be very difficult to lay down many general rules respecting them. It may, however, be observed that those species which are destitute of legs, and are of a fleshy consistence, have the body generally of a white, or dirty white colour. Many caterpillars also, which greatly resemble each other, produce moths totally unlike, whilst moths, which are so closely allied that it is almost impossible specifically to distinguish them (the shark moths, genus *Cucullia*, for instance), are different in their larvæ, which are consequently resorted to as affording a more certain specific character. Caterpillars also vary in their colours during their growth; and Mr. Sheppard has observed, that the skin of the caterpillar of the privet hawk moth, after being under ground four days, was changed

from a vivid green to a dull red. A similar change of colour also occurred in a caterpillar of the puss moth (*Cerura vinula*), which we endeavoured to preserve. From what has been said, it will be easily conceived that the colour of the caterpillar affords no criterion for judging of the colours of the future moth: the most beautifully coloured larvæ, as Reaumur observes (mem. 1. page 198), producing the dullest coloured moths; and *vice versa*. De Geer has, however, given two instances in which the moth preserves the colours of the caterpillar: these are the magpie moth (*Abraxas grossulariata*, figured in our article *ABRAXAS*), and the green *Pyrallis prasina*. Dr. Harris, in his memoir upon the salt marsh caterpillar, also notices that there are two varieties of the moth corresponding with the caterpillars from which they are produced; from the dark caterpillar and brown cocoon proceeds a moth with ash-coloured wings, and from the lighter coloured larva and cocoon is disclosed a moth whose upper, and also sometimes the lower, wings are white, these colours not designating the sex. De Geer also observed that the brown caterpillars of the yellow underwing moth (*Triphana pronuba*) produce males, and the green ones females.

Respecting the growth and size of larvæ, it is to be observed as a general rule, that they are longer and heavier than the perfect insect. According to the Count Dandolo, the following is a statement of the progressive increase in the weight of silkworms.

	Grains
A hundred worms just hatched weigh about	1
After the first moulting	15
After the second moulting	94
After the third moulting	400
After the fourth moulting	1628
On attaining the largest size	9500

From what we have already advanced in our observations upon the principles of metamorphosis, it will readily be conceived that with this rapid growth a continued shedding of the skin must be required. Hence we find caterpillars are subject to a greater or less number of these changes of the skin. The great garden tyger-moth (*Arctia carya*) undergoing as many as ten such moultings, *Arctia dominula* nine, *Arctia villica* from five to eight. The ordinary number, however, appears to be three or four, although it would seem that the grub of the bee, and many other footless grubs, undergo no moulting, although both Reaumur and Swammerdam assert that the contrary is the case. We have already, in our observations upon the general principles of the metamorphoses, noticed the peculiarities which occur in the caterpillar immediately previous to and during its moulting. We may therefore add, in order to complete the subject, that, quitting its former skin, the caterpillar appears very languid, and its body is soft and easily injured; it speedily, however, resumes its strength, and has increased so much in size that it appears extraordinary how it could have been packed in its former covering; its wonted voracity returns, and it now feeds with redoubled energy, as if to make up for the time which it had lost.

In this manner, and for a certain period of time, the growth of the insect is continued. The period which is required for the arrival of the larva at its full size is very variable. Perhaps the most general rule is, that insects are annual in their generations; either being hatched in the spring from eggs deposited in the preceding autumn, and becoming chrysalides in

the course of the summer, and arriving at the perfect state in the autumn; or else passing the winter in the chrysalis state, and bursting forth as perfect insects in the spring, and then depositing eggs, the progeny of which will not require to undergo their change to pupæ until the autumn: the duration of the larva state of these latter will therefore necessarily be longer than in the former; but there are exceptions to these rules; thus, in many species there are many generations in a year, as in the *Aphides* and the flesh-flies; whilst, on the other hand, some larvæ, as those of the goat-moth and cockchafer, require three years before they attain their full growth, and the stag-beetle is stated by Rosel to extend to six years.

Having at length attained its full size, the larva is now to undergo a change more important than any to which it has hitherto been subject.

III.—*The Pupa.* The change to which we alluded at the close of our last section consists in another shedding of the outer skin, when the insect appears in a totally different form, during the period of which it is destined to remain in inactivity and liable to destruction, were it not for the admirable instinct which is exhibited by the larva before its change, in the construction of a case or cocoon, wherein it is safely lodged until its final assumption of the perfect state. We have already, in our article *Cocoon*, given a general statement of the proceedings of the cocoon-forming caterpillars. There are also many larvæ which, although the pupæ are inactive, do not construct cocoons, but merely secrete themselves in some obscure situation, or bury themselves under ground, where they hollow out a narrow cave for their repose. Others again, as detailed in our article *BUTTERFLY*, suspend themselves in the open air. Another class, as described in our article *DIPTERA*, retain their larva skin within which they become pupæ. This period of inactivity is not, however, universal, since there are many insects which retain their activity, and therefore need no cocoon for their defence. This is the case with the grasshopper, cockroach, *Cimex*, *Cicada*, and others.

The state to which the insect is now arrived is technically termed the pupa; and it is this term which we must be compelled to make use of in speaking of the present state of insects, since there is no English word applicable to pupæ in general. The terms *Chrysalis* and *Aurelia* having indeed been applied to the pupæ of *Lepidoptera*, and that of nymph partially to other pupæ.

The variations which exist in the pupæ of the different groups of insects are much more striking than those observable in the larvæ; hence it is not surprising that Fabricius and his followers employed the name which characterises the pupa to designate the general nature of the metamorphosis, a decidedly incorrect mode of proceeding; since by this means the metamorphosis of an insect is said to be perfect when the pupa state is perfect (that is, active, and resembling the perfect insect, except in wanting wings); whereas it must be evident that this kind of metamorphosis must, as compared with other species, be the least perfect or complete; and, on the other hand, the imperfect metamorphosis, or that having the most imperfect pupa, must for the same reason be the most complete and perfect change which any of the insects undergo.

Linnaeus first applied these and similar terms, and most appropriately, to designate the variations, not of the nature of the metamorphosis, but of the pupa.

They were as follows:—

1. *Pupa completa*, active, with all the parts of the perfect insect. Example, *Aranea*, *Acarus*, *Oniscus*.
2. *Pupa semicompleta*, active, resembling the parent, but having only rudiments of wings. Example, *Gryllus*, *Cicada*, *Cimex*, *Libellula*, *Ephemera*.
3. *Pupa incompleta*, inactive, but with rudimental wings and legs. Example, *Apis*, *Formica*, *Tipula*.
4. *Pupa oblecta*, with the thorax and abdomen distinct, enclosed in a scaly covering, i. e., *corticata*, and either naked or enclosed in a cocoon. Example, *Lepidoptera*.
5. *Pupa coarctata*, enclosed within a globular or oval case, formed of the skin of the larva. Example, *Musca*, *Estrus*.

Now the true winged insects necessarily suffer only the four latter species of metamorphosis; although in those species of the semicomplete kind, which have no wings in the perfect state, it may with equal propriety be said that they belong to the first section in which the pupa is complete; these, however, must be regarded only as exceptions, belonging in reality to the second and not to the first section. Latreille, to whom entomology is so much indebted, distinguishes three species of metamorphosis, to which, with a view to obviate the difficulties arising from the Fabrician mode of nomenclature, he has applied a different series of names, calling the first *Metamorphosis inchoata*, *dimidiata*, and *perfecta*. The first of these terms is applied to wingless insects, such as the *Scolopendæ*, *Iuli*, &c., and in which the variations of the larva and pupa states are so indistinct that the terms cannot with propriety be employed, the metamorphosis consisting occasionally of an increase in the number of limbs and rings (figs. 27, 28, magnified; and 29,

natural size, representing the growth of an *Iulus*). In the species undergoing the metamorphosis dimidiata, the differences are more observable; the larva (demi-larva, Latreille) is apterous, but the pupa (demi-nympe, Latreille) is furnished with the rudiments of wings. This division, therefore, corresponds with the section *Pupa semi-completa* of Linnaeus, or the *Metamorphosis semi-completa* of Fabricius.

Fig. 30. Larva; 31. Pupa of the great green English grasshopper. See article GRASSHOPPER, for figure of its Imago.

The *Hemiptera*, *Orthoptera*, and many *Neuroptera*, undergo this kind of transformation; but amongst the latter there are some—and they are chiefly aquatic, such as the dragon-flies and may-flies—which are furnished with anal or lateral plates or gills for breathing

in the water; these, therefore, require to be formed into a distinct division, the preparatory states bearing in fact less resemblance to the imago than those species which are terrestrial in their larva and pupa states, breathing by spiracles, and greatly resembling the imago. As it is evident, however, that the latter undergo a less decided metamorphosis than the former, we must place the species which have the more decided semi-complete pupa at the head; indeed Mr MacLeay has separated the others, and applied to their changes the term metamorphosis sub-semi-completa.

Figs. 32, Larva; 33, Pupa; 34, Imago of *Ephemera vulgata*.

The third or total metamorphosis (*Met. perfecta* of Latreille) consequently consists of the Linnæan groups having incomplete, obtect, and coarctate pupæ. These are to be regarded as separate divisions. Amongst these pupæ some resemble the perfect insect, but contracted, and as it were destitute of life; they have limbs, it is true, which are separate from each other, but these limbs, as well as the entire body, are covered with a membranous skin. This covering exists in the other pupæ, but is of a firmer consistence, imitating a kind of bark, and to which the term *corticata* may be applied, and more completely enclosing the limbs in one general covering. To this kind of metamorphosis, which Latreille considers as comprising the obtect and coarctate pupæ, he has applied the term pupa obvoluta, observing that the expression *obecta* applies to both, and that that of *coarctata* is too vague; but surely the structure of the dipterous coarctate pupa (i. e., an incomplete pupa enclosed in the skin of the larva) is much more analogous to the structure of the true incomplete pupa (of which some species, as those of museum beetle, *Anthrenus*, are actually enclosed within the skin of the larva) than it is to the obtect pupa of lepidopterous insects; indeed it appears quite evident that if the coarctate section must be sunk at all, it must be in favour of the incomplete, and not the obtect, section.

Figs. 35, Larva; 36, Pupa obecta; 37, Imago of a butterfly (*Hipparchia pumilius*).

The existence and the number of legs of the larva,

the permanent or variable form of the head, the comparative structure of the organs of the mouth with those of the imago, the number of the spiracles and disposition of the tracheæ, the moultings of the skin, and the quiescent or active state of the pupa, are all important considerations, upon which the distribution of insects from the characters of their metamorphosis may be effected.

Hence the *Lepidoptera* are distinguished by the number of legs, scaly head, &c., of the caterpillar (*Eruca*, Latreille), and the obtect, or, as Latreille prefers calling it, the mummy-formed pupa (*Chrysalis*, Latreille); the *Diptera* are distinguished by their worm-like larvæ (*Vermilarva*, Latreille), and their

Figs. 38, Larva; 39, Pupa coarctata; 40, Imago of *Strahomy chameleon*.

more or less oviform pupa (*Pupa*, Latreille); the *Coleoptera*, *Hymenoptera*, and some *Diptera*, by the scaly head of the larva (*Larva*, Latreille), and the disengaged limbs of the pupæ (*Nympha*, Latreille);

Figs. 41, Larva; 42, Pupa incompleta; 43, Imago of *Chrysomela populi*.

and the *Orthoptera*, *Hemiptera*, &c., by the active imago-like larva (*Demi-larva*, Latreille), and active pupa (*Demi-nympha*). Thus by an ingenious arrangement we have the following distribution of metamorphosis:—

1. *Metamorphosis inchoata*, equivalent to the Linnæan section, having complete pupa.
2. *M. dimidiata*, semi-complete pupa.
  - A. Respiration in larva tracheal. *Gryllus*, &c. (*M. semi-completa*, Fabricius).
  - B. Respiration in larva branchial. *Ephera* (*M. sub-semi-completa*, MacLeay).
3. *M. perfecta*. Preparatory states, *Semi-larva* and *Semi-nympha*, Latreille.
  - A. Pupa with detached limbs, *P. incompleta*, Linnæus. Preparatory states, *Larva* and *Nympha*, Latreille. (*Coleoptera*, &c.)
  - B. Pupa mummy-shaped, *P. obecta*, Linnæus. Preparatory states, *Eruca* and *Chrysalis*, Latreille. (*Lepidoptera*.)
  - C. Pupa concealed by an egg-shaped covering, formed of the skin of the larva, *P. coarctata*, Linnæus. Preparatory states, *Vermi-larva* and *Pupa*, Latreille. (*Diptera*.)

Mr. Newman, in the Memoir already alluded to, has given another and equally ingenious arrangement of insects from their preparatory states; the names of his groups are, however, like those of Linnæus, founded merely upon the nature of the pupa state; and therefore cannot be applied as characteristic of the general metamorphosis. His arrangement is as follows:—

*Amorpha*, in which the penultimate state is provided neither with mouth nor organs of locomotion; consequently it neither eats nor moves, neither does it bear any resemblance to the perfect state.

1. *Lepidoptera*. 2. *Diptera*.

*Necromorpha*, in which the penultimate state is provided with mouth and organs of locomotion detached from the body, but so enclosed in a case that it can employ neither. The resemblance, therefore, to the perfect insect is very considerable, excepting in total want of motion.

3. *Hymenoptera*. 4. *Coleoptera*.

*Isomorpha*, in which all the stages are active and voracious, and of a similar form.

5. *Orthoptera*. 6. *Hemiptera*.

*Anisomorpha*, in which appear the amorphous, necromorphous, and isomorphous characters, together with a typical and distinct character.

7. *Neuroptera*.

The *Amorpha*, although thus divided into the two orders *Lepidoptera* and *Diptera*, are said to be divisible from the metamorphosis into two distinct sections, separated by the fact of their possessing or not possessing, in the penultimate or quiescent state, the last skin of the antepenultimate or previous state. Those which retain such last cuticle are termed *Amorpha dermatata*, and those which do not retain such skin are termed *Amorpha adermata*, an evident misnomer, since if they do not retain this last mentioned skin, they still are clothed in their own. But in the following page we are informed that the *Amorpha adermata* actually "retain two distinct coverings, thus resembling the *Amorpha dermatata*." When, however, we look more strictly at the character of the metamorphosis of these groups, and observe the ill effect which its employment has in reference to the natural distribution of insects, we shall at once see that this distribution, ingenious as it is (especially with reference to the septenary classification of insects, maintained by its author), and indeed any distribution of insects from the character of metamorphosis alone, evinces the absolute necessity of recurring to other characters. Thus, whilst one division of the *Amorpha* comprises the *Diptera* with true coarctate pupa, the other comprises not only all *Lepidopterous* insects, but also many *Diptera*, which must be more nearly allied to the other *Diptera* than they are to the *Lepidoptera*. Moreover, even amongst the adermatous *Diptera*, many species exhibit a necromorphous rather than an amorphous appearance; when, however, we regard the real character of the coarctate pupa (which corresponds with the *Amorpha dermatata*), we are at once confirmed that the real character of the dipterous pupa is necromorphous and not amorphous. The pupa of the bee is truly necromorphous; its larva forms, or else is by its parents or their assistants (neuters) enclosed in a cell, where it is safely guarded; so that it has only to cast off its skin and appear in its naked, defenceless, but yet defended state. But the flesh-fly is differently situated. Its functions in nature are such,

that the least waste of time would be to their prejudice. We have accordingly seen that in its first production this is amply provided against, although in what certainly appears to be an anomalous manner, (see our articles, *BLUE-BOTTLE-FLY*, and *BLOW-FLY*.) During its growth as a larva it undergoes no moultings of the skin, which are attended in other insects with a certain loss of time, and on arriving at its full growth the same character is still retained. The skin is not cast, but, with the most admirable foresight on the part of the Great Contriver of both great and small, becomes an envelope answering all the purposes of a silken cocoon or a waxy cell, and serves for the defence of the defenceless inhabitant enclosed within, and which, when carefully examined, proves to be a truly necromorphous pupa.

But there are other insects belonging to the necromorphous section, which indisputably prove the real identity of these apparent differences, and shew the necessity of looking at the subject in the most general manner. Thus some coleopterous pupæ (example the *Staphylinidæ*), and some hymenopterous pupæ (example, the *Chalcididæ*), are as truly mummy-formed as the lepidopterous pupa, whilst other coleopterous pupæ (example, *Anthrenus*, *Attagenus*) do not quit the larva skin, and are, therefore, amorphous. Again, some necromorphous pupæ (example, the *Trichoptera*), although inactive during a great part of their remaining in that state, become as active, previous to assuming the perfect state, as any of the isomorpha; and lastly, if we carefully examine the obtected pupa of a butterfly, we shall at once perceive that the only character which separates it from the necromorphous, or incomplete pupa of a beetle, is, that its limbs are laid more compactly upon its breast, each, however, being inclosed in its distinct sheath.

The preceding considerations appear sufficiently to prove that the pupa state of insects is a distinct state, and that instead of being regarded merely as the matured state of the larva, it would be more correct to regard it as the immature state of the imago. This will be still more evident from a more precise investigation of the form and structure of pupæ.

1. Of those species which undergo the metamorphosis *inchoata* of Latreille, the pupæ differ only from the preceding state by an increased size, and occasionally an increase in the number of segments. Crabs, spiders, centipedes, lice, spring-tailed insects (*Thysanuræ*), are subject to this kind of metamorphosis, which is so slight that it is impossible to decide whether one of these animals has arrived at its perfect state or not; and hence, as Fabricius observed in his *Philosophia Entomologica*, it is probable that many supposed species of spiders, &c., have been formed out of the immature states of these animals.

But there are some insects belonging in reality to the winged tribes, but forming an exception by being destitute of wings in the perfect state; such are the bed bugs, many individuals of *Velia*, *Hydrometra* and *Gerris*, likewise numerous *Phasmidæ*, and other apterous *Orthoptera* and *Hemiptera*.

2. Of those species which undergo the metamorphosis *dimidiata* of Latreille, the pupa has been most appropriately termed semi-complete by Linnæus, we therefore cannot approve of the alteration of this term to sub-incomplete, proposed by Burmeister: the pupa being intermediate between the larva, in which the body is completely apterous,

and the imago, in which it is furnished with fully developed wings: and being active like the larva, and provided with these organs, but so wrapt up as to be easily enclosed within four short cases, which arise in pairs from the back of the second and third segments of the body. Here belong the tribes of locusts, grasshoppers, mantes, cockroaches, earwigs, bugs, and treehoppers, in all which the resemblance of the pupa to the imago is very distinct. Here, also, are generally arranged the dragon-flies, and the may-flies (*Ephemera*), but in these groups the likeness of the pupa to the imago is less distinct, the organs of respiration being quite different, as above noticed, and the structure of the mouth being totally dissimilar. These groups, accordingly, are said by Mr. MacLeay to undergo a sub-semi-complete metamorphosis. There is another peculiarity connected with this species of metamorphosis, which sufficiently proves that here we are intermediate between the merely rudimental and the perfect metamorphosis, and that the perfection of the animal is not so dependent upon metamorphosis as in the subsequent perfectly metamorphic division. Thus there are many species belonging to this section, which remain throughout their life in a state of imperfection; of this, a common instance

Figs. 44, Apterous imago; 45, Winged imago of *Velia rivulorum*.

occurs in the Hydrometridæ, or water measurers. These insects, which are to be observed skimming along on the surface of the water, are generally found destitute of the slightest rudiments of wings; they, however, continue their kind, but occasionally certain individuals will be found in company with them with the wings fully developed. Now it is impossible to regard the former as pupæ, because they have no rudiments of wings; neither can we consider them as larvæ, because they are as large as the winged individuals, and are able to propagate. Accordingly they have been generally regarded as distinct apterous species; but a more extended investigation of these groups of insects will prove the specific identity of these imperfectly developed, but still perfect\* (as regards their powers of propagation) individuals with the winged specimens. Thus, there are many species, which, instead of being generally wingless, are furnished with short rudimental wings, and which are nevertheless capable of reproduction; hence, as well as from the structure of the rudimental wings, it is evident that they cannot be pupæ, and yet it occasionally happens that in a few individuals the wings are fully developed; thus the specific identity is not questioned, why then should it be in the former? the principle in either case being identical.

3. In those species which undergo the perfect metamorphosis of Latreille, the pupa is incapable

of eating and walking, and may be considered as a most characteristic state of the insect's existence. Here belong the tribes of *Coleoptera*, *Hymenoptera*, *Trichoptera*, and many *Neuroptera* and *Diptera*, having an incomplete pupa; the *Lepidoptera* having an obteated pupa, and the remainder of the *Diptera* and *Strepsiptera* having a coarctate pupa. We have already noticed the distinction of these kinds of pupæ; but as they all (including the coarctate pupæ when examined without reference to the external covering formed of the indurated skin of the larva) resolve themselves into one general mode of construction, that of being inactive, and having the limbs folded more or less closely upon the breast, it will be convenient to examine them in one general view. Here, then, we find the form of the future insect much more visibly impressed upon the insect than during its previous state; the head, thorax, abdominal segments, and the various limbs, are more or less discernible. The external covering in this state is variable in its consistence, according to the situation in which the pupa state is undergone; thus in those species especially belonging to the coleopterous, hymenopterous, and dipterous orders, which are safely protected from external injuries, the pupæ are soft and the envelope membranous; but in the *Lepidoptera*, and more especially those which are naked, the pupa (chrysalis) is of a hard texture. We have already, in our article CHRYSAIDS, given some general observations which are applicable to the construction of this state, and which it will be unnecessary to repeat. A clear idea of the arrangement of the limbs in the three principal divisions of incomplete, obteated, and coarctate pupa, will be obtained from the following figures, in which the same letters refer to the same organs throughout: fig. 46 representing a coleopterous,

Fig. 46. Pupa of the great water-beetle (*Hydrous piceus*).

fig. 47 a lepidopterous, and fig. 48 a dipterous pupa; the latter stripped from the cocoon-like skin of the larva. The letter *h* referring to the head,

Fig. 47. Pupa of the tortoise-shell butterfly (*Vanessa urticae*).

*t* the thorax, *a* the abdomen, *a a* the antennæ, *e e* the eyes, *m* the mouth, *p* the palpi, *w* the upper wings, *w w* the posterior wings, *||||* the legs.

It must, however, be borne in mind, that in these pupæ the limbs have not yet acquired their

\* "The true criterion of animal as well as vegetable perfection is the ability to continue the species."—Mac Leay's *Horn Entomologicæ*, p. 446.

full size, and the abdomen is not yet reduced to the size which it will possess in the imago state.

Fig. 48. Disengaged pupa of *Stratiomys chamæleon*.

Pupæ are ordinarily of an elongated oval form, the thickest part being towards the head; the body is generally smooth, but in some instances various spines or hairs are to be observed upon various parts of the body; and others, especially the chrysalides of butterflies, are angulated, as described in our article *CHRYSALEIS*. In some aquatic pupæ, as described in our article *CHIRONOMUS* and *CULICIDÆ*, the back of the front part of the thorax is furnished with exserted breathing organs. The structure of the terminal segment of the body is also variable; one of the most remarkable variations, essentially serviceable in effecting the suspension of suspended chrysalides has been described in our article *BUTTERFLY*; and it may here be noticed that in those species of *Hymenoptera*, which have the ovipositor long and exserted, it is generally curved upon the back of the abdomen, although in some it is stretched out at

Fig. 49. Pupa of an *Ichneumon* and *Callimome*

length. In many of the wood-boring species of *Lepidoptera*, (as, for instance, the Goatmoth) the abdominal segments of the pupa are furnished with transverse ridges of minute hooks, which are serviceable to the insect, when about to assume the imago state, in working its way to the orifice of its burrow, the hooks, by the alternate contraction of the abdominal rings, being employed as anchors in preventing the insect from falling backwards.

Fig. 50. Lateral view of the pupa of the goat-moth, lettered as Nos. 46, 47, and 48; and T 1, T 2 and T 3, being the three thoracic segments; XX, two of the rows of hooks.

There is a curious circumstance connected with the development of the insect structure, especially interesting as regards the pupa state of insects, and it is one which has hitherto received but very little attention. In the larva state the body is composed of the ordinary and typical number of

segments, but in the perfect state some of the segments are not to be found. The change, therefore, must take place at the period of the insect's assuming the pupa state. Dr. Ratzeburg, indeed, accounted for the loss of one of these segments, by asserting that the head of the pupa of the bee corresponds with the head and first segment of the body of the larva; but this, as we have already said, is certainly inaccurate, as we have proved by direct observation, and as is further evidenced by the leg-bearing structure of the first segment in many larvæ. The loss must therefore occur in the abdominal segments; but upon this branch of the subject we require more direct investigations than have yet been devoted to its elucidation. As regards the segmental development of the earwig, an elaborate paper has lately been read before the Entomological Society, but it is not yet published.

Pupæ, in general, are of a dirty white colour when their situation is under ground, or in cases artificially constructed by the larvæ. Those, more especially which lie naked under ground, are of a dark bright brown, whilst those which are naked, and exposed to the action of the light, are more variable in their tints, some being gilded as in the aureliæ or chrysalides of butterflies.

The period passed by insects in the pupa state is very variable, the variations extending from a few days to as many years. Ordinarily, its extent is determined by the circumstances to which we have alluded in our observations upon the duration of the larva state; that it is chiefly dependent upon the temperature of the atmosphere. Providence has wisely ordained that the development of the perfect insect shall not take place until the season when proper food for its own sustenance is at hand, or a proper situation for the deposition of its eggs is to be discovered. Hence some insects are produced earlier, and others later, in the season; and in doubled brooded species, or those of which there are two generations in a year the early brood passes but a very short time in the pupa state, whilst the later brood remains throughout the winter as pupæ. Hence Reaumur was enabled by experiments with chrysalides to abridge or extend their lethargic state by the artificial heat or cold; the chrysalides of various lepidopterous insects, which would not ordinarily be produced until spring, being placed in a hot-house, and the butterflies being developed in the middle of the winter, the contrary effects being produced when they were placed in an ice-house. Hence it is evident that by the action of an increased temperature a certain evaporation of the fluid matter, with which the newly-formed chrysalis is filled, takes place; but we can by no means agree with Kirby and Spence, that "this necessary transpiration, other circumstances being alike, must take place sooner in a small than in a large pupa;" and, consequently, "that small pupæ continue in that state a shorter time than those of larger size:" indeed, we are disposed to question the correctness of the latter assertion, and to say, on the other hand, that the duration of the pupa state is totally independent of size. We could adduce hundreds of examples in support of our assertion, but it will be sufficient for our purpose to observe that the largest lepidopterous insect, the great Death's-head moth, requires, according to Harvarth, but one month at the end of autumn, when the weather has been comparatively cold, to undergo its pupa state. If

evaporation were the sole operation to which the pupa was subject, there would be sufficient grounds for the theory of evaporation entertained by Swammerdam, Reaumur, Kirby, and Spence; but such is not the case, for Reaumur having enclosed a pupa in a stopped glass tube, collected only several drops of water, which were condensed against the sides of the tube, the pupa having only lost one eighteenth part of its original weight. Hence the development of the organs of the enclosed animal, by absorption and assimilation, constitute the great operation which the pupa has to undergo, and this must, of course, be of equal duration, whether the insect be a large or a small one, although it may be accelerated or prolonged according to the degree of temperature of the atmosphere.

In our articles *CHRYALIS* and *ERIOGASTER*, we have noticed some curious and inexplicable circumstances relative to the retarding of the production of certain individuals for one or more years, although placed in precisely similar circumstances with others which are evolved at the ordinary and stated time. The same facts have been observed respecting other moths.

We are now to notice the mode in which the insect emerges from its pupa skin. Ordinarily this is effected as heretofore, in consequence of the increased size of some, at least, of the segments of the body, especially those of the thorax; and it is now only necessary for the insect to give to its enclosed body various contortions, when the skin splits generally down the back, and permits the escape of the enclosed insect. In chrysalides, the slit extends gradually down the sides of the wing cases, and on each side of the leg cases, so that the outer skin of the chrysalis may be said to be split into four portions; on its exclusion, the insect is soft, weak, and covered with moisture. The elytra and the wings, at first, are but of a small size; their form, however, soon changes, their thickness diminishes, and their ordinary size is acquired, the air tubes distributed throughout the body, and especially in the wing, performing the important office of inflation, and chiefly assisting in effecting the change, so that in a very short period the insect has arrived at its full size, and acquired the utmost perfection of all its organs.

Fig. 51. Tortoise-shell butterfly just emerged from the pupa.

The wings of lepidopterous insects, as they lie within the pupa skin, exhibit all the future markings of the butterfly and moth, but of course of a reduced size. The wings themselves appear perfectly flat, and it is difficult to conceive how these organs expand to their full dimensions, all these markings retaining their relative sizes. The difficulty is, however, remedied on denuding the wings of their

scales, when their surface is discovered to be entirely formed of an innumerable series of minute wrinkles, giving the wing an elasticity, by which we can stretch them to nearly double their size, by moistening them with water. If we imagine the scales to be placed upon the upper edge of each ridge, and that they increase in size as the wings expand, we shall be furnished with a further clue to the solution of this interesting question, as to the mode of expansion of the wings of the *Lepidoptera*.

In the aquatic pupæ, which produce aerial insects, it is necessary for the pupa to quit the water previous to putting on the perfect state; thus the pupa of the dragon fly creeps up the stems of some adjacent plant; and that of the gnat half protruding its body above

Fig. 52. Gnat emerging from its aquatic pupa.

the surface of the water, the skin splits down the back and the gnat, making use of its pupa case as a boat gradually draws itself out of its case, upon which it sits until its wings are expanded. In pupæ which are enclosed in cocoons or other cases, different modes of escape are required. How, for instance, can a moth, whose beautiful wings and crested thorax indicate no previous struggle, make its way through the cocoon, often as solid as the hardest wood. This is effected either by the peculiar construction of the cocoon, or by the operation of some fluid emitted by the insect on its arrival at the perfect state. In like manner the pupæ of flies and other coracate diptera force off a case, at one end of the dried skin, by inflating the middle of the head into a large membranous vesicle; and the pupæ of the caddice flies, which are inclosed in the case in which they resided whilst larvæ, make their way through the net work covering which they had spun to defend its entrance. But the most curious circumstance connected with this subject, is the mode of extrication of the males of the Gall insects (*Coccus*), the pupæ of which are strictly coracate, the imago making its escape backwards from beneath the flattened skin of the larva, its wings being turned backwards over the head.

The development of insects is very rarely attended with those deviations from the ordinary rule, which are sometimes met with in other tribes of animals. It has, however, been recorded in the *Entomological Magazine*, No. 12, that a male and female emperor moth (*Saturnia pavonia minor*) were produced from a single larva of an extraordinary size. Kirby and Spence also mention that, according to Kleesius, a German entomologist, two specimens of *Gastropacha quercifolia* (the pine lappet moth), were produced from one pupa, which was large, being full two inches long and one thick. These circumstances are sufficiently marvellous, but the most marvellous fact of all is that affirmed by Mr. Dale, in the *Magazine of Natural History*, Nos. 19 and 34, viz., that he "once had a

specimen of *Bombyx menthastri*, and six of *Ophion vinula*, hatched from the pupæ of *Bombyx vinulus*, which is certainly a curious fact." We presume from this statement, which is, however, sufficiently destitute of precision, that these various specimens were produced from a single pupa of the puss moth. On throwing off the pupa covering, the arrival at the perfect state is ordinarily completed; but a remarkable exception to this occurs in the *Ephemera*, of which we have given an account in our article upon these insects. We will, therefore, only add that this occurrence of a subsequent moulting in this group does not seem to warrant the conclusion, that the preceding state is not that of the pupa, nor to overthrow the opinion that the pupa state ought not to be regarded as a distinct one. We apprehend, indeed, that as the *Lepidoptera* and the dragon flies are known to shed a similar pellicle, its existence throughout the winged insects ought, from analogy, to be presumed, until direct observation proves the contrary.

We are now to examine

Section III.—*The general structure of insects as especially exhibited in their perfect state.* Our attention must now be directed to the final and perfect state of insects, and in the first place to their structural peculiarities. This branch of the subject will naturally divide itself into two branches, first, the anatomy of the external parts of the body; and secondly, that of the internal organs.

1. *External anatomy.*—Insects being animals destitute of any interior skeleton, it is necessary that their external covering should be much thickened, and rendered sufficiently strong to give support to the numerous muscles which are internally attached to it. Hence in the majority of insects this covering is of a scaly or horny consistence. It is, however, modified by the nature of the habits of the individual. Thus the *Aphides*, *Hemerobius*, *Ephemera*, and other short-lived insects, have the skin very soft; whilst those which generally take up their abode beneath stones, under the bark of trees, in water, &c., are more strongly defended against accidents by the solidity of their envelope, than those which live upon flowers. Those, also, which reside beneath the bark of trees, or under stones, have a flattened form, whilst those which burrow into wood are cylindrical.

The body of insects consists of a series of rings connected and articulating with each other, by the assistance of muscular membranes, whereby the insect is enabled to contract or lengthen, narrow or dilate, its body, and so give to it all the necessary movements.

We have said that the external integuments of insects exhibited a horny appearance, nevertheless there is no real analogy between the scaly covering of a beetle, and horn, their chemical properties being quite distinct; to be convinced of which, it is sufficient to apply them separately to the flame of a lamp; and the same distinction is proved by placing them in a solution of potash, of the temperature of boiling water, in which the horn will be dissolved; but the covering of the beetle undergoes no change, except that of loss of colour. The base of the latter is found, by chemical analysis, to consist of a peculiar substance, found only in the integument of annulose animals, which has been termed chitine, and which forms the outer covering; albumen also, an animal extract, a small portion of carbonate of potash, phosphate of lime, and phosphate of iron, and an oil variable in colour according to the colours of the organs from

which it is extracted, form parts of the insect integument, but chitine is by far the greatest portion of the materials of which it is composed.

By Linnæus, the body of an insect was divided into four parts, the head, trunk, abdomen, and limbs. The latter, however, more properly belong to the second of these divisions, of which they are appendages; and the term thorax is now generally applied to designate the Linnæan trunk. Hence we have now to treat upon the head, thorax, and abdomen. These three divisions, as respectively comprising the principal organs of sensation, locomotion and generation, appear to be completely in unison with nature, and have accordingly been universally adopted and employed. That persons ignorant of the comparative anatomy of insects should have blundered in their trivial descriptions of insects, and misnamed any of these parts, can be no argument against their correctness; neither can we at all comprehend the assertions of a recent author, who would impose, in lieu of this distribution, a useless (as it appears to us) series of names for each individual segment, stating that "their wings are either thoracical or abdominal appendages, as an entomologist pleases,"\* and that, therefore, there are no such parts in an insect as a thorax or an abdomen.

But in addition to these three primary divisions, the body of insects consists of a series of secondary divisions, or rings, of which the head exhibits no distinct trace; the thorax, on the contrary, is always divisible into three segments; and the abdomen is, in general, variable in the numbers of its segments from six to nine, exclusive of the organs of generation. On comparing the different segments of a perfect insect, various striking differences will be observed, depending principally upon the presence or absence of the appendages, or organs, which these segments respectively support, as well as upon the degree of their development. Thus when one of these segments has attained its greatest extent and complication, and the appendages, which it supports, have reached their maximum, it is presumed that the segment itself is composed of a certain number of distinct pieces, more or less distinct, with which it is essential to possess an acquaintance. To arrive at this result, it is evident that we must examine one of the thoracic segments in

\* Newman on the Osteology, or External Anatomy of Insects, a series of letters commenced in the Entomological Magazine, and containing a great deal of very valuable matter, but written in a style quite perplexing to a learner whilst endeavouring to unravel many of the statements which it contains. Thus, when the author asserts that the limits of the abdomen have been always ideal; that the abdomen may comprise either seven, eight, nine, ten, or eleven of the thirteen segments of an insect's body; and that, consequently, the wings of a beetle are generally considered abdominal; a tyro relying implicitly upon such a statement, would conclude that the researches of all previous anatomists had been of the most unphilosophical kind. Mr. Newman must, however, be well aware that there is not the least shadow of a foundation for them to rest upon. Linnæus and his followers, it is true, restricted the name of thorax in the beetles, to the first segment following the head, but did it thence follow that all the remaining segments must necessarily be abdominal? This would, indeed, be the case, if Linnæus had divided the body of an insect into the head, thorax, and abdomen; but this is not the fact. He says, "corpus dividitur in caput, truncum, abdomen, artus;" and he subsequently gives the thorax as a compound part of the truncus, which he says is situated "inter caput et abdomen." Thus, by speaking of the term thorax, when used in its Linnæan, restricted sense, as though it had been used in its now most general sense for the whole Linnæan truncus, the learner is left in doubt; and all preceding authors made to appear absolute fools, and yet the author himself is enabled, by the researches of these very men, to gain credit for having introduced a most philosophic simplicity into the science of insect anatomy, with the majority of his readers.

preference to the others, because they are most fully developed, and most complicated in their structure. The pieces composing one of these segments are divided by M. Audouin, who devoted a great deal of attention to this branch of the subject, into three distinct kinds, dorsal, lateral, and ventral. Mr. Mac Leay, however, considers them only as dorsal and ventral, uniting the lateral with the ventral. The ventral portion consists of a simple piece, of which the form is very varied; this is named the sternum. Attached internally to this piece, at its posterior margin, is another single piece, variable in its form, but generally resembling the letter Y, and appearing necessary for the support and protection of the nervous system. This piece, as being attached to the head, thorax, or abdomen, is respectively termed the entoccephalus, entothorax, and entogaster. The lateral pieces are more complicated, each being composed of two pieces; the one, anterior, articulating with the sternum, and directed upwards, constituting the episternum, behind which the other is situated, and which is in connexion with the base of the leg, and is called the epimeron. The upper surface of the thoracic segment is also composed of a number of distinct pieces, which are respectively named prescutum, scutum, scutellum, and postscutellum, and which successively follow each other. Such is supposed, theoretically, to be the structure of each segment of the body of the insect; and the fixed number of parts thus discovered, is supposed to exist in all annulose animals, sometimes being distinct as when the segment has reached its maximum of development, but still more frequently more or less rudimental, or soldered to adjoining pieces, as required by the variation of development. Some pieces may even entirely disappear, and the segment may appear to consist rather of a single piece, or, on the contrary, of two or even a greater number of segments united together. Modifications of this kind are traceable not only in different insects, and in the different segments of the same insect, but even in any single determinate segment, when examined in the various states of the same individual. The comparative examination of these segments of the insect skeleton has singularly simplified the anatomical study of these animals, placing it upon a firm basis, and more rigorously compelling the precise determination of organs which had previously been either entirely overlooked, or had only been regarded without reference to the analogous formations of other insects; and hence to any organ which happened to be singularly developed, a name was given without the least reference to the comparative structure of other insects, or the same comparative parts in the other segments of the same individual.

It would carry us too widely into the field of theoretical inquiry, were we to show that the head, and various abdominal segments, were organised in a manner strictly analogous to those of the thorax; neither could they be done effectually without a reference to the typical structure of annulose animals in general—a vast and difficult subject of investigation. We will, therefore, now confine our attention to

*A—The head, or the seat of the organs of sensation.*

The head, or first segment of the body, is united to the anterior part of the thorax by a distinct articulation, and may be considered as a kind of solid corneous case or box, having an opening in the centre of its anterior part, where the mouth is placed. It is of a triangular or oval shape, with the narrowed part

advanced in front, the middle of the opposite side, or base, being occasionally prolonged into a neck. But there are numerous modifications of this form, and the head is often buried as far as the eyes in the prothoracic cavity. On minutely examining the skull, it will be found that it consists of several regions. These are, the epicranium or skull-cap, composing the greater part of the head, of which it chiefly occupies the upper and posterior part. This is bounded in front by the clypeus (*c*), or shield of the mouth which generally lies above the parts of the mouth (*m*) and the under side of the head is covered by the jugulum, or throat. At the sides of the epicranium are situated the large compound eyes (*e*), between which, when present, the ocelli (*o*), or simple eyes, are placed, and the antennæ (*a*) are inserted nearer to the mouth. But all these parts will require a more precise examination.

Figs. 53, Head of *Dytiscus*; 54, ditto *Oxycheila*; 55, ditto *Helio-cantharus*; 56, ditto *Acanthothorax*.

The head is generally of a corneous, or coriaceous texture, although at times it is membranous or vesiculose; and its form is modified from oval, or globose, to longitudinal, heart-shaped, compressed, cornuted, rostrated, &c. The parts of the epicranium, and its frontal part, the clypeus, have been variously regarded and named by different authors. Thus Kirby and Spence divide the upper surface of the head into the nose (*rhinarium*), hind nose (*postnasus*), forehead, crown, occiput, cheeks, and temples, and the under surface into the lora and jugulum; and it is not to be denied that, in the numerous modifications which occur in the form of the heads of insects, there are to be found portions developed to an extent, and to which, from their analogy with the parts of the head of the higher animals, it may seem serviceable to give analogous names; but it is impossible to limit the extent of these parts; and therefore a general definition could only be applied to each; as, that the forehead is that part of the head which is between the eyes, and when the head begins to assume a flattened form; and the cheeks those parts which lie at the sides of the head between the eyes and the mouth. In many insects the head is united to the thorax by a membranous tube or neck, consisting, as in the *Diptera* and *Hymenoptera*, in which the motions of the head are very free, of the attenuated fore part of the thorax. In some beetles, however, the term neck is applied to a narrowed portion of the skull, which forms a kind of rotule, playing in the opening of the thorax.

The clypeus (*c*) of Fabricius, or the nose of Kirby and Spence, or the epistomis of Latreille, is an important part of the head, as occasionally, from its development, and the consequent want of development of the true upper lip (*labrum*), it takes the functions of the latter, and serves, as the name imports, and as it was at first employed by Linnæus in the lamelli-

corn beetles, as a shield for the mouth. That there are grounds for not strictly regarding it in every insect as a mouth-shield, cannot be denied; but it

Figs. 57, Head of *Brentus*; 58, ditto *Fulgora*, 59, *Apoderus*; 60, *Diopsis*.

would be equally incorrect to reject it on that account, as it would be to reject that of *labrum*, or upper lip, because the latter organ occasionally is quite unserviceable as a lip. Still less do we feel inclined to regard it as a nose. Its form is very variable according to the form of the head. Thus, in an elongated head, it will be distinct and square, or rounded; and in those with a shorter head it is transverse. In the rose beetle it has a deep frontal notch; in the sacred beetle it is ornamented with several scalloped notches; in the hornet it is subquadrate; in the grasshopper rounded; and in the rose beetle transverse.

The organs of sense affixed to the head are:—

*Fixed*—a The composite eyes.

b The ocelli, or single eyes.

*Moveable*—c The antennæ.

d The trophi, or organs of the mouth.

In relation to the mutual dependence of these organs upon each other, and upon the general character of the insect, we are sure that we cannot do our readers greater service than by quoting the following admirable passage, by Mr. Newman, from the *Entomological Magazine*:—"Professor Rang has prettily observed, that every instrument, whether it be for the generation or transference of power, has a best size and a best form. Nature, in the formation of her instruments, has always adopted that best size and best form. If her creatures wanted but to see, a globular eye floating in space might perhaps be the uniform character of the animal world; if to see and to eat, an eye and a mouth would be given; if to move swiftly in the air were desirable, wings must be supplied; if on earth, legs must be added; if in the water, fins. To carry all these organs, and to contain muscle to guide and govern them, a body must be added. Each part of the body will be of the best size and best form for the functions it has to perform. We have seen that insects in their larva state have a very uniform allowance of muscle to each segment. In the imago the charge of supporting the whole body in the air is entrusted sometimes to a single segment; and, in order to supply sufficient strength for the purpose, nature robs the neighbouring segments of their muscle, and gives it the one which needs it. In the head, the mouth-feelers and eyes operate in the same manner one on another. Observe the dragon-fly, the emperor of his tribe; his wings rustle as he hovers stationary and hawk-like in the air; his appetite is insatiable; his food the active occupants of his own element; it is given to him in charge to set bounds to the increase of the insect race; he beholds his prey afar off; he darts on it like the rapidity of a

lightning flash; to devour it ere life is departed is the work of an instant; he sails round and round; he soars up and down; when the sky is serene, he seeks his prey, like the swallows, almost beyond the reach of human sight. What organs does such an animal require? Are they not these, eyes, mouth, and wings? How has nature provided for his wants? Regard his head—below, it is all mouth; above, it is one continuous eye. Contemplate his wings—their character is strength and lightness, power and activity. His body is slender and graceful; like a rudder, it serves as an instrument wherewith to shape his course. Porrected feelers, whether cranial, lateral, or maxillary, would be comparatively useless to an animal whose dependence for support is on the keenness of its vision and the velocity of its flight. We find them but little prominent; his every organ of the required size. The same law obtains as certainly and unvaryingly in form. There is truly a best form and a best size, and Nature always provides both."

a. *The composite eyes.*—The eyes of insects, unlike those of the higher animals, are immovable, horny, and unprotected by any eyelid, of a large size, and placed at the sides of the head, sometimes entirely occupying the sides, and sometimes being so extensive that scarcely any other part of the head is left perceivable; moreover, it is a curious circumstance, that the eyes are sometimes clothed on the outer surface with fine bristles. These organs are generally hemispheric, and of a circular, oval, or kidney-shaped form; and when more closely examined, they

Figs. 61, Head and eyes of the bee; 62, Part of the faceted portion showing the hairs between the facets.

are found to consist of a very great number of minute hexagonal lenses, giving the eye a reticulated appearance. Each of these lenses operates as a distinct organ of vision, and hence the number of the eyes may be said to correspond with the exact number of these hexagonal facets; various calculations have been made as to the number of these organs. Muller has given a list of their number as derived from the observations of Swammerdam, Leuwenhoeck, Andre, Baster, Reaumur, Lyonnnet, Goetze, Puget, and Schelver.

	Lenses.
In the ant there are	50
In the convolvulus sphinx	1300
In the common house fly	4000
In the silk-worm moth	6236
In the goat-moth	11300
In the dragon-fly	12544
In a butterfly	17355
In a mordella	25088

And, according to a calculation cited by Geoffroy, there must be not less than 34,650 of such facets in the eye of a butterfly. When one of the eyes is de-

tached from the head and cleaned, the lenses are found to be as clear as crystal. Reaumur fitted one of them thus removed to a lens, and found that he was able to see through it distinctly, the object being, however, greatly magnified. Ordinarily the eyes are entire, but sometimes the antennæ are inserted so close to their inner margin that the eyes are thrown out of their ordinary form, and more or less surround the base of the antennæ. Sometimes even the eye is thus completely divided into two parts by the antennæ being inserted in the middle. The same thing occurs in both respects, when the lateral margins of the head become acute, in which case they enter the anterior limb of the eye, and either partially, as in *Dorcus*, or entirely, divide it in two parts; thus forming an upper and an under eye: hence these insects may be said to have four composite eyes, which in fact appears to be the case in the whirlwig-beetles (*Gyrinus*), and in the males of some May-flies (*Ephemera*).

Figs. 63, Head of *Coptocephalus*; 64, ditto of *Tetraopes*; 65, ditto of *Dorcus*; 66, ditto of *Ephemera bioculata*.

Ordinarily the eyes are sessile, that is, attached by their entire breadth to the head; but in some instances they are placed at the extremity of footstalks formed of a continuation of the corneous covering of the head, and consequently incapable of separate motion. This is especially the case in the dipterous genera, *Achias*, *Diopsis* (fig. 60), *Plagiocéphala*, and others, in some of which the footstalks are nearly as long as the entire body; the same occurs in some species of strepsipterous insects, as well as in some exotic bugs (*Heteroptera*). Again, the eyes of insects are generally either almost flat, or but very little elevated above the surface of the head (fig. 53); but in many cases they are almost globose and very prominent (fig. 54), a peculiarity respecting which, and connected with their habits, has been noticed by the late celebrated Swedish entomologist Dalman, who observes that the very prominent eyes of insects generally indicate their habitation to be either in sandy situations or upon the margins of water; this is exemplified in the coleopterous genera, *Cicindela*, *Elaphrus*, *Omophron*, and *Stenus*, and in the hemipterous genera, *Salda* and *Aldus*. Moreover, insects with prominent eyes seem to be especially rapacious in their habits, as in the genera above mentioned, *Libellula*, *Hemerobius*, &c.

In many dipterous insects a remarkable diversity exists in the size of the eyes in the two sexes, those of the males being very large, and united upon the crown of the head, whereas those of the females are much smaller, leaving a space between them upon the top of the head (figs. 67 and 68). The same also occurs in the male hive-bee.

In some insects, however, the eye appears to be completely wanting; this is asserted to be the case in the remarkable parasitic insect, thence named *Braukacra*, in the genus of beetles, *Clididium*, Kirby; and

in the ants forming the genus *Ponera*. In like manner we have been unable to observe the least trace of eggs in more than one exotic species of ant; and in some of the *Centipedes* the same is stated to be the case.

Figs. 67, Head of male; 68, ditto of female *Syrphus*.

#### b. The Ocelli or Simple eyes (o in the figures).

These organs (sometimes also named *Stemmata*) are minute nearly globular lenses placed upon the crown of the head or the forehead, between the upper region of the eyes. Unlike the composite eyes, they are often entirely wanting, and are never present in the image unless as accompaniments to the latter. In their organisation they appear to be similar to the lateral point-like eyes of caterpillars or the eyes of spiders. In general they are three in number, placed in a triangle, or more rarely almost in a line. Occasionally, however, there are but a pair of these ocelli, as in many lepidopterous insects, where they are present, although concealed by hairs, in the mole-cricket, in many bugs and smaller frog-hoppers (*Cercopidae*); in some of the sand-wasps (*Larra*, &c.) the hinder pair are almost obsolete; and in some of the coleopterous insects, belonging to the family *Dermestidae*, there appears to be but a single ocellus. They appear in the ants to be connected with the development of the sexual character, since the neuters are entirely destitute of them. They are also entirely wanting to the great mass of *Coleoptera* (having been only noticed in a few small *Brachelytra*, *Paussus cruciatus*, and some of the *Dermestidae*), in many bugs and water-bugs, and also in many neuropterous insects. That these ocelli are in fact supplemental eyes, appears evident from the experiments of Swammerdam and Reaumur; the latter of whom varnished the back of the head, covering the ocelli, in more than twenty bees, which he then set at liberty three or four paces from the hive, but not one of them knew where to find it again, nor appeared to search for it. They flew at random to the adjacent plants, but never to a distance; and though they seemed to have no difficulty in flying, he never saw them rise in the air as those did whose faceted eyes he had varnished over. The internal anatomical structure of the ocelli also proves that they are distinctly organs of vision.

#### c. The Antennæ (a in the figures).

We are now to turn our attention to a pair of organs perhaps the most characteristic of the insect tribes. These are two articulated appendages of a most variable character, affixed at the sides of the head, and generally between the eyes and the mouth. Although occasionally wanting, and generally rudimentary in the preparatory states, these organs are never absent in the imago state. We shall have occasion subsequently to enter into the question of the use of these organs, which have been the subject of much dispute amongst naturalists. It will be sufficient here

to notice that they are exceedingly sensitive, and are evidently of the highest degree of service to the insect. From their great diversity of structure they are employed by entomologists as affording the most satisfactory characters to distinguish the various genera, &c. It is therefore essential that we should enter more into detail respecting their peculiarities. We will therefore describe them according to their various distinctions, and, first, of their situation.

Antennæ are inserted into the head, and connected therewith by means of a ball and socket-like articulation, arising generally in the face between or beneath the eyes; sometimes also, as already described in treating of the eyes, they arise within a notch on the inside of these organs, which are sometimes thereby entirely divided into two parts. They are likewise, as regards their connexion with each other, contiguous or inserted close together, so as almost to touch each other, or distant when far apart; sometimes they arise from a produced part of the head, serving either solely as a peduncle for their support as in the dipterous genus, *Ceria*; or as an elongated rostrum as in the weewils (fig. 56), at the extremity of which the mouth is placed, the antennæ being inserted at its sides; or as a footstalk for the eyes as in *Diopsis* (fig. 60), in which the antennæ are placed close to the eyes; whereas in *Achias* they are frontal, and the eyes pedunculated.

As to their composition, they are formed of a variable number of small and generally cylindrical pieces, externally covered with a horny or leathery integument, according to the general consistence of the body of the insect; and internally softer or vesiculose, having an internal cavity extending throughout the whole length of the organ, inclosing nerves for sensation and muscles for motion; thus forming a series of tubes connected by a membrane, and attached end to end, varying often as to their respective forms, and having generally but a common motion. As to their form, antennæ may be regarded as equal or unequal, according to the equality or inequality in the length of the respective joints: they may also be regular or irregular, accordingly exhibiting a uniform appearance, or having the various joints irregularly constructed. Definitions of a few of the more important modifications of form will be serviceable to the beginner, who would otherwise have to contend against a series of technical names which would be unintelligible to him, unless acquainted with the Latin language, from which they are generally derived.

Variouly formed Antennæ.

*Filiform*, when the antennæ are of equal thickness throughout their whole length, like a thread (fig. 69).

*Setaceous*, when they insensibly diminish in thickness to the tip (fig. 70).

*Moniliform*, when they are formed of globular joints resembling a necklace of pearls (fig. 71).

NAT. HIST.—VOL. II.

*Cylindrical*, when they are of equal thickness throughout, with the joints scarcely discernible.

*Prismatic*, when they resemble a prism, or are formed of three sides (fig. 72).

*Ensiform*, angulated at the sides, large at the base, but gradually terminating in a point, like a sword (fig. 73).

*Subulata*, short and pointed at the tip.

*Fusiform*, narrowed at the two extremities and thickened in the centre, like a spindle.

*Aristate*, when the antennæ are terminated by a fine bristle (fig. 74).

*Dentate*, when the joints are armed with short spines (fig. 77).

*Serrate*, when the joints are triangular, one of the angles being internally produced, like a saw (fig. 76).

*Pectinated*, when the joints are furnished with a long and slender tooth, generally arising from the base or extremity of each, thus resembling a comb (fig. 78).

*Bipectinated*, when each joint produces two long teeth, or filaments.

*Flabellated*, when the branches are very long and flattened like the rays of a fan (fig. 78 beneath).

*Ramose*, when several of the joints throw out branches (fig. 79).

*Furcate*, when the antennæ are divided into two branches like a fork (fig. 80).

*Geniculated*, when they are bent at an angle, generally at the extremity of the long basal joint, like an elbow (fig. 81).

*Clavate*, when they gradually thicken to the tip like a club (fig. 82).

*Capitate*, when they are terminated by a knob-like mass or head.

*Perfoliate*, when the terminal joints of the club are not closely applied to each other.

*Lamelliform*, when they are terminated by a club greatly produced on one side, the joints of which form plates applied against each other (fig. 83).

*Fissile*, when they are terminated by a cleft knob.

*Plumose*, when they resemble a feather (fig. 84).

*Auriculate*, when one of the basal joints is dilated into a shield or ear partially covering the rest (fig. 85).

*Palmated*, when the antennæ are short, and divided by deep incisions.

*Nodose*, when they are thickened in various parts, like knots.

*Verticillate*, when whorls of hair are placed at equal distances upon the joints (fig. 86).

*Fasciculate*, when a bundle of hairs is placed on one side of each joint.

*Scopiferous*, when a single or very thick bundle of hair is placed upon one of the joints.

H H H

As to their size, antennæ are exceedingly variable, as they are also in their length, being sometimes shorter than the head, and at others several times longer than the entire body; in many instances they are as slender as a hair, and at other times nearly as thick as the body. As to their direction, they are generally projected in front of the head; others throw them over the back; in some they are stiff, in others flexible; they are straight, deflexed, or spiral, and are often, when at rest, lodged in particular cavities prepared for their reception on the under side of the head or thorax.

The number of joints of which these organs are composed, merits a few observations. Coleopterous insects have in general eleven joints; the *Heteroptera* from four to six; the stinging *Hymenoptera* twelve in the females and thirteen in the males; but in the *Lepidoptera*, *Ichneumonida*, *Orthoptera*, and many others, the number of the joints is much more considerable, sometimes reaching fifty or sixty; and in some *Orthoptera* the number is much more numerous.

In a few insects the antennæ are very short and destitute of joints, as in the *Hippoboscidae*, and in Dalman's genus *Articerus*: *Bi-articulate* (two-jointed) antennæ are found in *Paussus*, triarticulate antennæ in many *Diptera*. The large sawflies (*Cimbices*) vary in the number of their joints from five to eight.

It still remains to be noticed, that a very great diversity often exists in the structure of the antennæ in the opposite sexes of the same species; this is especially noticed in the greatly increased length of these organs in the males, and in the various hairs, feathers, or branches with which they are adorned in this sex. Numerous other variations occur, such as the incrustation of certain of the joints, or their greater development, to enumerate which would occupy too great a space; but in all which these advantages are always in favour of the male sex.

#### d. The Mouth\*.—(M in the figures).

If the structure of the antennæ has required a considerable portion of our attention, a still greater share must be now devoted to the various and variable organs of which the mouth of insects is composed, since it is upon these variations that the most valuable arrangements of insects hitherto proposed, have, in a great measure, been established. If a beetle and a butterfly, a house-fly, or a bug, be examined whilst feeding, a totally different apparatus will be found in each, although perfectly adapted for the mode of feeding. The beetle is employed in gnawing and tearing in pieces hard or fleshy substances: its instruments of manducation are therefore horny and robust. The butterfly, on the contrary, has to suck its food at the bottom of the tubes of flowers, and here in the glowing beams of the sun it revels in its existence, and sips the most delicious nectar. It is necessary for this purpose that it should be provided with a long and slender instrument; but, from the very structure of this apparatus, it is essential for its defence, that so soon as the insect has ceased feeding, the instrument should be lodged in a place of safety. It is therefore rolled up in a beautiful spiral direction and laid to rest between a pair of hairy appendages

which will defend it from injury. If we observe a common fly sipping up a drop of spilt wine, or reveling upon a morsel of sugar, it will be found that its mouth is totally unlike either of the former, it is short, thick, and fleshy, and acts as a sucker, the nutriment ascending through the canal which runs upwards into the throat. The disgusting bug, and all its brethren, have a mouth still differently constructed, being a long and slender-jointed canal of a fleshy or leathery substance, but furnished internally with several slender bristles, which the insect employs as lancets to wound its prey. In the flea again the structure is quite different.

Fig. 87 Antlia of *Lepidoptera* (*Sphinx*).

These insects may be cited as affording examples of the chief variations which occur in the general structure of the mouth, and to each of which, as a variation of the mouth, a name has been applied. Thus the mouth of the butterfly and other lepidopterous insects (fig. 87), is termed by Kirby and Spence antlia; by Fabricius lingua (an evidently exceptionable term, being only strictly applicable to a single organ of the mouth); and by Latreille, spirignatha. The mouth of the fly (fig. 88), is termed by Kirby and

Proboscis of *Diptera* (*Tabanus*).

Spence, Linnæus, and Fabricius, proboscis. The mouth of the bugs (fig. 89) is denominated by Kirby and Spence, a promusculus; but by Fabricius, Olivier, and Latreille, rostrum, a term more properly applicable to those insects which have the head produced in front into a beak or snout, as the weevils or scorpion-tailed fly (*Panorpa*), but which latter Latreille, for distinction, terms proboscirostrum. The mouth of the flea is termed a rostrulum, by Kirby and Spence; and rostellum, by Latreille, the latter name having been proposed by Kirby and Spence for the suctorial organs of the louse tribe (*Pediculidae*), but which Latreille terms siphunculus. Moreover, the mouth of the bee, which is chiefly organised upon the same plan as the biting mouth of the beetle, but has its parts elongated so as to lap up the honey of flowers, is termed by Latreille a *Promusculus* (although that term had been given by Kirby and Spence to the mouth of the bug tribes).

Throughout this great variation of structure, however, the strictest uniformity is maintained, the same

\* *Obs.*—In the various figures representing the mouth of insects, the same letter indicates the same organ throughout; *l*, is the upper lip, labrum; *m* mandible; *mx* maxilla; *ip* maxillary palpi; *c* chin or mentum; *l2* labium, or lower lip, *lp* labial palpi; *t* tongue, lingua or paraglossæ.

number of parts existing in all, although occasionally rudimental or modified in various degrees, so as to

Promusci of Hemiptera (Pentatoma).

correspond with the functions which they have to support. As, however, these modifications of structure are permanent throughout entire groups, serving, in fact, for the establishment of orders, according to some authors, it would surely be absurd to deny the propriety of assigning to each variation a distinct and fixed name.

The mouth of the hexapod winged insects being thus composed of a certain number of parts, may much more easily be referred to one general type of form, than the mouths of the other annulose animals, some of which have a much more complicated organisation of the mouth than is to be found in insects; thus in the crabs we find not less than five pairs of jaws, whereas there are but two pairs of these organs in insects.

The parts of which the mouths of all insects is composed, may be reduced to six; namely, four lateral pieces disposed in pairs, and two other organs opposed to each other, but in an opposite direction, and which meet each other, so as to close the mouth

The different parts of the mouth of a beetle (Blaps). *l1*, upper lip; *m*, mandibles; *mx*, maxillæ; *mp*, maxillary palpi; *c2*, chin or mentum; *l2*, labium; *lp*, labial palpi.

from above and below; the upper one being placed above the upper pair of lateral organs, and the lower one below the under pair of lateral organs.

As regards the mode of taking their food, insects have been divided by many authors into two groups; namely, those in which the mouth is furnished with mandibles fit for biting, and those in which the mouth

is suctorial. All the various modifications of form to which we have above alluded may be referred to one or the other of these sections; and it is upon this character that the leading division of insects into *Mandibulata* and *Haustellata* has been adopted by various authors; although, since in one period of an insect's life its mouth is fitted for biting, and in another for sucking honey (as in butterflies), it may perhaps be alleged that too great a weight has been assigned to the structure of the mouth. The jaws of biting insects have a horizontal motion; the mandibulated insects must, of course, be characterised by the horizontal motion of their jaws, and not as might, perhaps, from the names of the two groups, be supposed, upon the presence of mandibles in the *Mandibulata*, or their absence in the *Haustellata*; because, as we have already said, the mandibles or their representatives are to be found in all insects. It would, indeed, perhaps be advisable to propose other terms in lieu of these, but as they are generally understood, we shall continue to speak of the mandibulated and haustellated insects, when we would distinguish them by the biting or sucking mode in which they take their food.

Moreover, instead of treating of these two groups separately, as has been generally done, it will perhaps be more advantageous, as enabling us more readily to show the modifications, which each organ undergoes, to take the various organs seriatim—prefacing their description by the following general observations.

In biting insects, or those which feed upon solid matters, the four lateral pieces perform the office of jaws, and move in a horizontal direction, the two other pieces being regarded as lips; the upper jaws are more particularly denominated *mandibles*; and the lower jaws are named *maxillæ*, and, in general, each of the latter is furnished with a slender-jointed appendage termed a *palpus*, which is never found attached to the mandibles of winged insects; in some annulose insects the mandibles are, however, also palpigerous. The *maxillæ* are generally terminated by two lobes, the outer one being very variable in form. The upper lip is termed the *labrum*, and the lower lip *labium*; but the latter is a much more complicated instrument than the former, and is furnished, like the *maxillæ*, with two short articulated palpi.

In the sucking insects, the nutriment being essentially fluid, the necessity for biting jaws is obviated. They are therefore either obsolete or they assume the form of lancets, and as such have a motion quite different from that of the jaws of biting insects. The mouth of these insects exhibits two distinct modifications of form. In the first, the four lateral pieces, or the mandibles and maxillæ, are converted into slender, setiform, or lancet-like pieces, forming a kind of sucker, which is received into a membranous conical or cylindrical and articulated gutter, as in the bugs; or are lodged within a thick, elbowed, and fleshy sheath, as in the flies. In the second modification, the upper lip and the mandibles are either obsolete or but very minute; the lower lip is no longer a distinct and loose organ, but is attached to the head, and is distinguished only by a pair of large palpi; the maxillæ, on the contrary, are greatly elongated, but very much attenuated, being transformed into two tubular threads, which, uniting at the edges, form a kind of sucker, generally rolled up in a spiral direction, and furnished at the base with two minute palpi. We will now

take the organs of the mouth seriatim, according to their position, commencing with that which lies uppermost, or,

*The Labrum or upper lip* (*l* in the figures).—This organ is, in biting insects, a horny or leathery flattened plate of variable form, attached, by an articulation, to the clypeus, and serving as an upper covering to the

Figs. 91, Labrum of *Megacephala*; 92, ditto of *Aploa*; 93, *Perilampus*; 94, *Banchus*.

rest of the mouth; unlike the lower lip, this organ is never furnished with palpi. In many insects, however, it is quite membranous, and is in such cases completely concealed by the clypeus, with which, indeed, it was sometimes confounded by Fabricius, who also gave to it the name of that part. It is generally fringed with hairs. In some few *Hymenoptera* it is furnished with a slender appendage, to which indeed Illiger applied the name of *labrum*. In the *Hemiptera* the upper lip is in the form of an elongate triangle, which falls upon the base of the canal of the lower lip. In the *Lepidoptera* it is so minute as not to be discernible without great care, appearing as a small triangular piece extending downwards towards the base of the labial palpi. In the *Diptera* it is either obsolete, or exists in the shape of a corneous slender gutter, hollowed beneath, and receiving the other slender lancet-like organs.

*The Mandibles, or upper jaws* (*m* in the figures).—These organs, in the generality of biting insects, are the chief instruments by which the food is bitten into

Figs. 95, Mandibles of *Therates*; 96, ditto of *Hyboma*; 97 ditto *Mamelia*; 98, ditto *Goerius*.

pieces. They have been considered analogous to the jaws of the higher animals, but they have a much greater resemblance to a pair of large and robust, horny, and notched teeth. They are inserted at the sides of the oral aperture immediately below the lower lip, to which, indeed, they appear to bear the same kind of relation as the lower jaws do to the lower lip. They are composed of a single piece, and are destitute of any appendage. In some of the *Brachelytra* (especially the species ordinarily termed the devil's coach horse, fig. 94) their inner surface is, however, furnished with a small moveable exarticulate process, as is also the case in *Pussalus* and *Hydrous*. By Linnæus they were termed *maxillæ*. In beetles these organs are generally of large size, and of a horny substance. The large and powerful instruments with which the head of the stag-beetle is armed are the mandibles immensely developed; but these organs, like many others, exhibit great variations according to the sexes. In the last-named insect for instance, the jaws of the females are so short that this sex was long regarded as a distinct species. They are usually symmetrical, but in many cases are dissimilar in form, and more particularly in the structure of the teeth, with which

they are commonly furnished. In some of the lamellicorn beetles, the internal base of these organs is dilated into a broad and flattened square plate, having numerous transverse ridges, serving for the purpose of bruising the leaves upon which these insects feed (fig. 97). In some beetles also, which subsist upon the juices of flowers, or upon the flowing sap of wounded trees, &c., the jaws are of a membranous structure, and quite unfitted for mastication. In the *Hymenoptera* also, the jaws, although of the ordinary form, cannot, in many cases, be regarded as masticating organs, but appear solely to be employed either in the construction or the provisioning of the nest. In the *Lepidoptera* they are very minute, membranous, and triangular, and placed on each side of the labrum. In the *Hemiptera* they are very long, slender, and employed in conjunction with the maxillæ as lancets. They have also the same character in the *Diptera*; but here they are often entirely wanting. They are, however, particularly distinct in the gnats and gadflies (*Tabanidae*) fig. 88, *m*.

*The Maxillæ, or lower jaws* (*m x* in the figures).—These organs are two in number, and are placed beneath

Figs. 99, Maxilla of the great water-beetle (*Hydrous piceus*) seen from above; 100, from below; 101, from the back.

the mandibles, from which they differ in their less firm consistence and more complicated structure, being formed of several parts, and especially by the possession of a slender articulated appendage or palpus, attached to each. They appear to be more especially connected with the lower lip, serving, in some instances, as a sheath for its defence; in the beetles, however, they are generally quite detached. In a table of the comparative variation of the chief insect organs, Mr. Mac Leay has shewn that the maxillæ are less liable to vary than any other; hence it is important to note the modifications to which they are subject.

The maxillæ appear typically to consist of five pieces, exclusive of the maxillary palpi, at least those maxillæ which are the most complicated in their structure, exhibit this number of parts. They are the cardo or hinge (figs. 99, 100, 101 *a*), a most appropriate term, designating a transverse horny piece by which the jaw is affixed within the mouth by membranes. Strauss calls this the *branche transversale*. Savigny the support, Burmeister the base, and Newman the insertio. This piece is especially distinct in beetles and bees. The two following pieces (*b* & *c*) are closely soldered together, and compose the horny pillar between the basal hinge and the terminal lobes. Of these two parts, the external portion (*c*), as first noticed by Latreille, and since named *la pièce palpifère* by Strauss, and the *squama* by Burmeister, bears at its extremity the maxillary palpus (*f*); the internal or dorsal piece\* (*piece dorsal* of Strauss-Dürckheim, *b*)

\* Mr. Newman appears to restrict the term maxillæ to this piece.

occupies the space between this and the membrane which runs parallel therewith, forming the basal part of the internal terminal lobe (*d*). Conjointly these three pieces (*b*, *c*, & *d*) are termed the stipes or stalk of the maxillæ by MacLeay and Kirby. The last of these, or the fourth piece of the maxillæ (*d*), is more important, extending not only along the internal side of the maxillæ, but extending often considerably beyond the former pieces, and being very variable in its form; its terminal portion (*dd*) has been named the internal lobe of the maxillæ by MacLeay and others, but it is not distinct from the basal part (*d*). In the predaceous beetles it is long, slender, curved at the tip, and internally clothed with fine hairs or bristles, and sometimes terminated by a hook, which is occasionally articulated, as in the tiger-beetles.

Figs. 102, Maxilla of *Cicindela*; 103, ditto of *Bombus*; 104, ditto of *Blatta*; 105, ditto of *Melolontha*.

This part is termed the *piece intermaxillaire* by Strauss-Dürckheim, and lacinia by MacLeay. In some biting insects it is of a very large size, as in the bees, in which it forms the sole terminal lobe of the maxillæ (fig. 103); in many instances, however, it is greatly reduced in size, not extending beyond the base of the palpus, in which case another organ is developed at its expense, which, as in the large water beetle (*Hydrous piceus*), joins the terminal part of the maxillæ (figs. 99, 100, 101 *e*). In the predaceous beetles this external lobe, as it is generally called, is often of equal size with the terminal portion of the lacinia, or the internal lobe, and is here articulated both at its base and in the middle (fig. 102 *ee*), and is generally termed thence the internal maxillary palpus. In the order *Orthoptera*, this same outer lobe is equally developed, but is not articulated, except at the base (fig. 104); its inner surface is somewhat hollowed, so that it falls upon the terminal lobe of the lacinia, and defends it laterally. It is hence termed by Fabricius the galea, a term applied theoretically by Strauss-Dürckheim to the outer lobe of the maxillæ of all insects. In many insects the two lobes are soldered together into a large flattened membranous plate; numerous other variations of form occur in these two lobes, which, from their situation, are necessarily the part most serviceable to the insect, and consequently modified and adapted to the functions and habits of each of these variations; perhaps the most remarkable are those exhibited by some of the leaf-devouring lamellicorn beetles, in which the extremity of the lobes are very broad, horny, and armed with several strong teeth, having somewhat the appearance of a large double tooth (fig. 105), and by some other beetles which feed upon the pollen or honey-flowers, and in which the outer lobe of the maxillæ are nearly half the length of the body. In the stag-beetles it is prolonged into a fine pencil of hairs, serviceable in licking up flowing sap. It is at the external extremity of the stipes, and intermediate between

it and the base of the outer lobe of the maxilla, that the *palpus* (for *mp*) of each maxilla is attached. This is a slender appendage, somewhat similar in its construction to the antennæ, but much shorter, and composed of fewer joints, varying in the latter respect from one to six articulations; the latter number is often found in the *Hymenoptera*, but in the *Coleoptera* four appears to be the prevalent number. In the *Orthoptera* and *Trichoptera* it is generally five. These palpi vary very considerably in the size and form of their respective joints, although they are generally slender and filiform; hence they are eminently serviceable in characterising genera, now that naturalists have discovered that smallness of size does not form an objection to the value of the characters derived from an organ. In the suctorial mouth, the maxillæ are still important organs, although completely changed in the structure; thus, in the *Lepidoptera* (see fig. 87), they constitute the two long and very slender instruments which compose the tubular and, when at rest, spiral apparatus, which the insect employs for collecting honey. That these instruments are really modified maxillæ is proved by the modifications which these organs undergo, even in the biting insects, and likewise by the possession of a minute palpus attached to each at the base, which in most *Lepidoptera* is so small as to be easily overlooked, being concealed by the hairs of the labial palpi; in other moths, especially in some of the *Pyrilidæ*, they are, however, very distinct; and hence these insects are ordinarily described as having four palpi. In the *Diptera* and *Hemiptera* the maxillæ are horny, setiform, or lancet-shaped. In the former order they are sometimes almost obsolete, and are generally furnished with a palpus, varying in the number of its joints from five to one, but in the latter they resemble the mandibles, and are not palpigerous. In the flea they are dilated and palpigerous. In the *Trichoptera* they are rudimental, but furnished with long palpi.

*The Labium, or lower lip.*—We have now arrived at a very complicated organ, which generally serves to

Figs. 106, Labium of *Carabus* outside; 107, ditto inside; 108, ditto laterally; 109, ditto of *Necrophagus*; 110, ditto of *Dytiscus*.

close the mouth from beneath, and therefore corresponding with the upper lip. This organ, if regarded analogically, with reference to the structure of the mouth of other annulose animals, appears to be composed of a pair of maxillæ, united together internally, furnished with a pair of palpi, and covered, in a great measure, by a large horny plate, which is generally termed the mentum. The parts of which this organ is composed are numerous, and the greatest confusion has arisen in the works of authors, as to their nomenclature, owing to the numberless modifications which they undergo, whereby the relative proportions and the consequent relations of the various parts with each other, and with the head, are greatly altered. On

examining the under side of the head of a beetle, the parts of which this lower lip will be found to consist are, first, a broad horny plate (*ch* or *c 2*) articulated at its base, and connected at its extremity by membrane, with a leathery piece (*l 2*), within which arises a fleshy organ (*t*), occasionally having its anterior angles elongated (*t t*); the labial palpi (*l p*) take their rise between the first and second of these pieces. The first named piece is attached to the head by a horny piece (*z*), which, although apparently articulated in some beetles (as for instance in the cock-chaffer, the common Chinese *Mimela*, &c.), is immovable, and forms a portion of the throat or jugulum, but which MacLeay regards as part of the lower lip, and calls it stipes. It is the piece *prebasilaire* of Strauss-Dürkheim. Mr. Newman calls it mentum and insertio, and regards it both as a terminal part of the throat, and as a basal part of the lower lip; at least if we understand him correctly, which it is certainly difficult to do, from the abrupt manner in which his definitions of these organs of the mouth are drawn up. The chin, or mentum (the broad horny piece above-mentioned), is very variable in its form (*ch* or *c 2*), sometimes, as in the lamellicorn beetles, serving exactly as a lower lip, and closing the mouth; but in other beetles it is shorter and more transverse, and cannot be in the least degree effectual in performing this office. Sometimes even its base is soldered to the jugulum, the stipes being entirely obsolete, and thus, in fact, becoming the anterior edge of the former. This is the case in *Pausus*, *Siagona*, &c.; but its true nature may be known by the position of the labial palpi, which always arise between its extremity and the base of the terminal portion of the lower lip, to which (if with MacLeay, Kirby, Curtis, &c., we continue the analogy with the human face), we must restrict the name of lower lip or labium, although the same name is applied to the whole apparatus. This difficulty may be obviated by terming this piece, with Fabricius and others, ligula. The latter piece is more membranous, and of a smaller size than the mentum, and often serves to close the mouth as effectually as the former. We therefore see no sufficient reason, on this account, for not giving to it the name of the labium, or lower lip. The form of this organ is very variable, and sometimes, as in the tiger-beetles, it is completely concealed by the mentum. On examining the lower lip, internally, a distinct membranous or leathery lining (*t*) will often be found, the angles of which are protruded beyond the front margin of the lower lip, in the form of little protuberances (*t t*). These are very conspicuous in many *Carabidae*, and are termed paraglossæ, although they can only be regarded as the produced angles of the internal organ, which, from analogy, may be termed the lingua, or tongue, and which is very distinct in many orthopterous, and some neuropterous, insects; in which orders the general structure of the labium (and its various parts) is very similar to that of the beetles, except that in the former, the part to which we have restricted the term labium (or ligula) is divided, longitudinally, into four branches. In the *Hymenoptera*, however, the labium has reached its fullest development; and this is more especially the case in the bee tribes, to which (without going through the other hymenopterous families) it will be advantageous to direct our attention. We have said that in these tribes the maxillæ co-operate with the labium, in order to enable the insect to suck the nectar of flowers.

The machinery by which the lower parts of the bee's mouth (to which, from analogy, the term tongue is

Figs. 111, Labium of *Geotrupes*; 112, ditto of *Melolontha*; 113, ditto of *Cicindela*; 114, ditto of *Gryllus* outside; 115, ditto laterally.

often, but not very correctly, applied) are protruded, is exceedingly beautiful. It has, however, already been described at length in our article, *BEE*. On referring to vol. I, p. 361, col. 2, the maxillæ, and their very minute palpi, will be observed to be extended on each side of the central piece, which, it will be seen, arises from a short triangular piece, which appears analogous to the part which we have noticed above, as the stipes of MacLeay, although here, for evident purposes, it is articulated and moveable. The next piece is the thickened horny tubular piece, or mentum, at the extremity of which arise the labial palpi, remarkable for the elongation of the two basal joints, and between which, at the base, are two short processes, which are termed paraglossæ; the apparatus terminating in a long and slender many-ringed instrument, which, in the following page, we have called the tongue, or lingua, but its true analogy has not been determined. By some authors it is called the labium.

In the lepidopterous insects, the structure of the mouth, although having a function similar to that of the bee's, is completely altered as to the form of its individual organs. In the latter, the maxillæ and labium conjointly operate in sucking up honey; but in the former (see fig. 87), the maxillæ (*m x*) alone perform this office, the labium (*l 2*) being rudimental, and attached to the head, and only distinguishable by bearing the pair of large palpi (*l p*) which bend upwards, and form the defence of the spiral maxillæ. In the *Diptera* (see fig. 88), on the contrary, as well as the *Hemiptera* (see fig. 89), the labium (*l 2*) is the most conspicuous part of the mouth, forming the elbowed and fleshy, or articulated and membranous, tube or canal, in which the other organs of the mouth are enclosed. In these orders, moreover, the labial palpi are obsolete; great variations occur in these orders, and especially in the *Diptera*, as regards the form of this lower lip; but it would lead us too great a length were we to notice them more in detail. The forest flies, *Hippoboscidae*, and the flea, exhibit other modifications of form of the lower lip.

Such are some of the more important organs with which Nature has supplied insects, for the due support of their existence. Of their uses we shall speak more at large when we come to treat of the physiology of insects, when we shall state our reasons for employing the terms antennæ and palpi, which indicate no decided use in preference to that of feelers, which is, by many authors, assigned indiscriminately

to these two kinds of organs. We will, therefore, only observe, that much still remains to be done, before we arrive at a perfect knowledge of the structure of the various organs of the mouth throughout the insect tribes. Savigny has effected much in clearing away the obscurity in which the subject had long remained; but there is still an ample field for the employment of a steady eye and hand, in dissecting, and especially in delineating the many modifications of form, to which the parts of the mouth have been so fully shown to be subject. Until this have been done in the most careful manner, it will not be easy to arrive at a true knowledge of the mode in which these modifications of form are effected, and which alone will enable us satisfactorily to trace the analogies of the various parts throughout the various orders.

B. *The Thorax, or seat of the organs of Locomotion.* This portion of the body lies between the head and the abdomen, and supports the three pairs of legs; and the two or four wings with which perfect insects are in almost every case furnished.

In the early efforts made by scientific entomologists, to determine the various parts of the body of insects, too much attention was paid to an organ when it happened to be fully developed, too little to the mode in which this development was effected. Thus it sometimes happened, that the same organ received various names, according to its extent of development; and it was not until a rigid attention was paid to the various forms which the same part exhibited in its various modifications, that a fixed nomenclature could possibly be applied. This has been especially the case with the thoracic segments of insects; and it is only within a very few years that entomologists have given any extended attention to this part of the subject, or have endeavoured to introduce a fixed series of names. Audouin, Kirby and Spence, MacLeay, and Burmeister, have especially laboured in this field, in which much still remains to be effected. Linnæus thus described this part of the body which he called the trunk,—"TRUNCUS, inter caput et abdomen, pedatus thorace, supra dorso, postica scutello, subtus pectore sternoque." In his descriptions, however, he applies the term thorax either to the large shield which covers the first thoracic segment in beetles, or to the entire trunk, as in the *Hymenoptera*. This mode of description was, notwithstanding its evident impropriety, and want of precision, adopted by most entomologists. Illiger endeavoured to correct this nomenclature, by giving to the trunk of Linnæus the term thorax, designating its upper part, thorax superior, and its lower surface, thorax inferior. Latreille, and others, divided this part of the body into three distinct sections, the two posterior of which, from bearing the wings, Chabrier united under the name *trunc alifere*, which Kirby and Spence adopted, naming these two segments alitrunk; and the first segment, which bears the fore legs (which these authors rather regard as arms or hands), manitrunk. This nomenclature has not, however, been adopted, although Strauss-Dürckheim adopts this division of the thorax, calling the first segment corselet, and the two others the thorax. Most of these authors, however, regard the three segments following the head, as sufficiently separate to require separate names. And the terms prothorax, mesothorax, and metathorax, originally proposed by Nitzsch, have been applied to them; indeed Audouin, MacLeay, and Burmeister, regard

them as segments of equal rank, but as conjointly uniting to form the thorax; whilst Kirby and Spence employ these terms for the upper surface only of the thoracic segments, giving to their under surfaces the names of antepectus, medipectus, and postpectus. MacLeay applies the term tergum to the upper surface, and pectus to the lower; thus we have "tergum of the prothorax, pectus of the mesothorax, &c." Burmeister, with more uniformity and philosophic acumen, gives the following series of names:—

Thoracic Segment.	Upper Surface.	Under Surface.
1. Prothorax.	Pronotum (T 1).	Prosternum (T 1).
2. Mesothorax.	Mesonotum (T 2).	Mesosternum (T 2).
3. Metathorax.	Metanotum (T 3).	Metasternum (T 3).

This being the most simple system of nomenclature hitherto proposed for these thoracic segments, we shall adopt it, leaving it optional for our readers to regard the segments, either as entirely distinct, or as conjointly constituting the thorax, or as divisible into two portions, corresponding with the manitrunk and alitrunk of Kirby and Spence. We will only observe that the blunders of unphilosophical describers of insects—who contented themselves, in many cases, with no more anatomical knowledge than would enable them to distinguish one species from another, and who have, consequently, employed names without knowing or caring for their precise meaning—can be no ground for disputing the existence of organs, still less for asserting, as has inconsiderately been done, that the researches of such men as Lyonnet, Léon Dufour, Chabrier, Herold, Strauss-Dürckheim, Savigny, Audouin, and MacLeay, "tend to illustrate a theory, in itself evidently false, rather than to find out and establish plain and solid truths."

The complicated machinery requisite for the due performance of the two chief kinds of insect locomotion, namely, leg-movements, including creeping, running, swimming, climbing, as well as prehension; and wing-movements or flying, and likewise the great volume required by the organs of motion themselves, have necessarily produced a great increase in the size of the three segments of the body forming the thorax, which in the larva state were but equal in size to the remaining segments; hence we find that the thorax in the perfect insect has become the most robust yet compact, as well as the most complicated in its structure, of all the body segments of an insect. Moreover, the great diversity in the organisation of the wings, and the occasional transfer of wing motion to a single pair of wings, this pair being either the anterior, as in the *Diptera*, or the posterior, as in the beetles, have necessitated a concurrent modification in the form of the thoracic segments according thereto, as well as similar modifications resulting from the varying motions of the legs.

It is further to be noticed, that the many parts of which the thorax is thus composed, were provided by entomologists with separate names, whereby the nomenclature of this part of the body has become very complicated, more especially as the same part has received more than a single name, according to the greater or less degree of its development. This has been more particularly the case in the "Introduction to Entomology," wherein, although Messrs. Kirby and Spence do not describe much more than twenty of its distinct component parts, about forty different words are used for them in the nomenclature of the thorax. The chapter on Orismology is nevertheless, as Mr. MacLeay observes in the Zoological Journal,

"more particularly valuable, and, making allowance for the nomenclature of parts, deserves the special attention of entomological students."

in the perfect insect varies very generally and considerably from what it was in the larva." We have

Figs. 116, Upper, and 117, under side of the thorax of a beetle (*Buprestis*). T 1 pronotum, (T) 1 prosternum, T 2 mesonotum, (T) 2 mesosternum, marked with lines to distinguish its boundary, T 3 metanotum, (T) 3 metasternum. a, head; A, abdomen; w 1, elytra; w 2, posterior wings.

Much of this confusion has been obviated by M. Audouin, who, from his admirable comparative investigation of the structure of the segments of the body, ascertained that they were respectively composed of the same essential parts, and consequently that the same series of names might be applied to each. The following is a table of the thorax, as theoretically supposed by him to exist in all insects.

Thorax. (Truncus, Linn., Fabr. and Kirby)	Prothorax. (Manitrunk, Kirby; Corselet, Strauss).	Tergum. (Pronotum, Burmeister; Prothorax, Kirby) T 1. Pectus. (Prosternum Burmeister. Antepectus, Kirby) (T) 2. Furca, called Antefurca.	{ Præscutum. Scutum. Scutellum. Postscutellum. Sternum. or h 1 Episterna. 1 or 1 1 * * * Epimera. k or k 1
	Mesothorax. (Meditrunk, Kirby; Prothorax, Strauss).	Tergum. (Mesonotum Burmeister. Mesothorax, Kirby) T 2. Pectus. (Mesosternum, Burmeister. Medipectus, Kirby) (T) 2. Furca, called Medifurca.	{ Præscutum. a or a 2 Scutum. b or b 2 Scutellum. c or c 2 Postscutellum. d or d 2 Paraptera. Sternum. hor h 2 Episterna. 1 or 1 2 Epimera. k or k 2
	Metathorax. (Protrunk, Kirby & Sp., Metathorax, Strauss).	Tergum. (Metanotum Burmeister. Metathorax, Kirby) T 3. Pectus. (Metasternum, Burmeister. Postpectus, Kirby) (T) 3 Furca, called Postfurca.	{ Præscutum. a or a 3 Scutum. b or b 3 Scutellum. c or c 3 Postscutellum. d or d 3 Paraptera. Sternum. hor h 3 Episterna. 1 or 1 3 Epimera. k or k 3

"It must not be imagined, however," observes Mr. MacLeay, "that the pieces of the thorax mentioned in the above table are all perfect and distinct in every insect. Pieces of the thorax may disappear, being evanescent owing to the great development of the contiguous segments, or by being confluent or soldered together with the next adjoining pieces. To know the pieces which are thus lost, it might be thought that on comparing the larva with the perfect insect, the position of the stigmata (spiracles) ought to afford some clue, but in truth these are unsafe guides; as it is well known that the situation of the stigmata

Figs. 118, pronotum; 119, mesonotum; 120, metanotum of a *Dytiscus*. In 118 the subsegments are confluent. In 119 and 120 the alternate subsegments are dotted to show their extent.

indeed found a clue for getting out of the difficulty above-mentioned, but from the little attention hitherto paid to the subject, another difficulty of a not less formidable but of a far more philosophical kind has presented itself, namely, that of proving, by careful study, the relations of the several parts in the different orders, and the variations they are subject to.

Figs. 121, prosternum; 122, mesosternum; 123, metasternum of a *Dytiscus*.

The total number of parts in the thorax, according to Audouin, amounts to thirty-six; but if the simple pieces, as the sternum, &c., be supposed to be divided by the medial line, the number will be fifty-two; and Mr. MacLeay, by supposing that each of the three sterna consists, like the terga, of four transverse pieces similarly divided by the medial line, causes the whole number of pieces in the thorax to mount up to seventy-two. Authors, however, who have looked at the composition of the thorax, without having any theoretical views to maintain, have found the really distinct number of its parts much fewer in number than either of the last named authors; thus Chabrier and Burmeister reckon only eighteen, Kirby and Spence twenty, and Strauss-Dürkheim twenty-two. We will now confine our attention successively to the primary segments of the thorax, and show the chief modifications which they exhibit, and then describe the organs of locomotion.

#### 1. The Prothorax (manitrunk, Kirby), T 1 & (T) 1.

—This is the segment which immediately follows the head; and precedes the segment bearing the anterior pair of wings. On its under side it bears the anterior pair of legs. It is generally larger than the head, and smaller or narrower than the following segment; the reason whereof is obvious, since it has only to support one pair of limbs, whereas the following supports two. It is to the upper surface of this piece, when most fully developed, that Linnæus gave the name of thorax. It is named by Kirby prothorax, by Audouin tergum, and by Burmeister pronotum. But the four dorsal pieces are here confluent\*, although, as in some locusts, their situation is indicated by transverse impressions across the prothoracic shield.

The size of the pronotum (T) varies very considerably as well as its form; thus whilst in the *Coleoptera*, *Orthoptera*, and heteropterous *Hemiptera*, it is of a very large size and forms a strong horny shield (see figs. 116, 118, T 1), sometimes produced over the whole body, and in others furnished with the most remarkable protuberances, as in many *Homoptera*, lamellicorn beetles, &c. In the *Leidoptera* and *Trichoptera* it is nearly evanescent, forming in the first of these orders a narrow ring. In some *Hymenoptera* it is more conspicuous, forming, as in *Xyphidria*, a narrow neck, by which the head is attached to the thorax. In this order, the front of the thorax is covered by a narrow plate (see figs. 124, 125, c 1), which often laterally reaches as far as the base of the wings. This is the collare of Kirby, who contends that it ought not to be regarded as a part of the prothorax. MacLeay, Burmeister, and others, however, give it as a portion of that segment, the former considering it as the scutellum of the prothorax, and observing that as these insects are essentially fliers, this piece of the prothorax is employed to add strength to the mesothorax in its support of the upper wings.

The under surface of the prothorax (T 1) consists of a central piece or prosternum (antepectus, K.), which is generally horny, and extends in a point between the fore-legs, as is especially the case in the spring beetles (Elateridæ), and two lateral pieces which are very distinct in the predaceous beetles. These are the epimera and episterna of Audouin, and sometimes the ora of Kirby and Spence.

In addition to the various horns or protuberances which arise from the prothorax, but which are only continuations of the external crust, there are several distinct appendages to be noticed. Of these, the legs are the most important, the basal piece of which often appears to form a constituent part of the prosternum, but is, nevertheless, moveable; the first pair of spiracles are also parts of the prothorax.

Moreover, in some of the longicorn beetles there is a pair of moveable spines (umbones, Kirby and Spence), arising at the sides of the pronotum; and in lepidopterous insects there is a pair of scales covered with hair, quite distinct from the wing-covers (tegulæ), and which the same authors term patagia,

or tippets; but which have been overlooked by all other authors except Chabrier, who first discovered

Figs. 124, dorsal view of the thorax of a wasp; 125, lateral view of ditto, lettered as in figs. 118—123.

them, or else confounded (as by Burmeister, p. 77), with the true tegulæ. They are described as vesicles appearing full of liquid and of air, and are placed at the sides of the pronotum.

2. *The Mesothorax*.—(*Prothorax*, Strauss-Dürckheim) T 2 and (T) 2.

This is the second segment of the thorax (or the first of the alitrunk of Kirby and Spence), and bears the anterior pair of wings, or their representatives, and the middle pair of legs. In insects which have the four wings of equal size, the mesothorax and the metathorax, (the following segment), are equally developed; but when, on the contrary, one pair of these organs is more particularly developed, the segment to which it is attached is consequently increased in size. If this pair of wings be the anterior pair, the mesothorax is greatly enlarged, this is, therefore, the case in the *Diptera* (fig. 126), where the mesothorax almost occupies the entire thorax. In the *Hymenoptera* (fig. 124) the second pair of wings exist, but of a smaller size than the fore pair; the metathorax is accordingly more developed than in the *Diptera*, but is smaller than the mesothorax. If we now look at those orders which have the second pair of wings enlarged, we find the mesothorax diminished, and the metathorax increased in size to a corresponding extent; this is the case in the beetles, but most especially in the extraordinary parasitic order, *Strepsiptera*, respecting which so much incorrect matter has been published.

The four pieces of which the upper side of each thoracic segment is typically composed, are sufficiently distinct in the mesonotum; the first, or the præscutum (a 2), (prophragma, Kirby and Spence); and

Figs. 126, dorsal view of the thorax of a *Tabanus*; 127, lateral view of ditto, lettered as in figs. 118—123.

the second, b 2, scutum (or the dorsulum, Kirby and

\* Hence MacLeay says, that in all future descriptions the four confluent dorsal pieces of the prothorax (which are almost invariably, at least in the *Coleoptera*, &c.) described as the thorax by the describers of species should no longer be called the thorax but the prothorax; but this must surely not be correct, since the latter name would imply both upper and lower surface of the first thoracic segment, although the descriptions are applicable only to the tergum or upper surface of this segment. Burmeister has obviated the difficulty by proposing the term pronotum.

Spence), are both distinct, but not conspicuous parts in the *Coleoptera*, in which order the third piece, (*c* 2), is very conspicuous \*, being the triangular part which is found at the base of the elytra, where they unite together, and is ordinarily termed the scutellum; but more properly the scutellum of the mesothorax or mesoscutellum. Some beetles, indeed, are said to be excutellated, or destitute of scutellum; and so far as its occupying the ordinary exposed situation is concerned, they are excutellated; but the same part is to be found in a diminished form in all beetles.

In some few insects, as the scutellata (*Tetyra*), the scutellum is so much enlarged, that it completely covers the abdomen. The postscutellum of the mesothorax, (*d* 2), or the *frænum* of Kirby and Spence is also distinct, but not very conspicuous, except by dissection.

In insects having the upper wings transformed into horny or leathery wing-covers, the mesoscutellum is very distinct and elevated, being evidently serviceable in giving some kind of support to these wing covers. In insects with membranaceous wings the mesoscutellum is not so conspicuous an organ.

The upper surface of the mesothorax is very variable in its consistence, according to the degree of exposure to which it is subject. Thus in the beetles, where it is almost entirely covered by the prothoracic shield, or by the base of the wing-covers, it is leathery, with the exception of the exposed mesoscutellum. If, on the contrary, it is naked, as in the *Hymenoptera*, *Diptera*, &c., it is more solid in its construction. In the *Diptera* the præscutum and scutum of the mesothorax are soldered together, see fig. 126, (*a* 2, *b* 2), forming the larger part of the upper surface of the thorax; the scutellum (*c* 2) is also distinct. In the *Lepidoptera* the præscutum is small, but the scutum (dorsum, Kirby and Spence) very large and distinct. In the *Hemiptera*, as in the *Coleoptera*, the præscutum and scutum are covered by the pronotum. In the *Hymenoptera* the scutum and scutellum are similar to those of the *Diptera*.

On the under surface the mesosternum is generally horny, and extends between the middle legs, sometimes as in some *Coleoptera* (*Elatridæ*), having an impression to receive the spine of the prosternum; at other times, as in the *Cetoniæ*, the prosternum itself is produced into a spine extending between the anterior legs.

On each side of mesosternum extend the epimera and episterna of the mesothorax, the former being termed scapularia by Kirby and Spence; they are generally of small size, except in a few instances, such, for instance, as the *Cetoniidæ*, in which the former are very conspicuous, forming the horny plate, intervening on each side between the shoulder of the elytra and the posterior angles of the pronotum.

In addition to the above pieces, the paraptera, or tegule, being the small scales at the base of the upper wings (see fig. 124, *o o*), which sometimes, as in some of the *Proctotrupidæ* (especially *Galesus*), are of a large size, must be noticed. They also acquire a large size in the *Lepidoptera*.

The mesothoracic appendages are the anterior pair of wings, the middle pair of legs, and the mesothoracic spiracles. In dipterous insects the base of the wings are often furnished with a membranous scale, termed the alula or winglet, which Kirby and Spence regard as the true analogue of the second pair of wings, and consequently as attached to the metathorax (see fig. 126 *y*).

3. The Metathorax, T 3 and (T) 3 (*Protrunk*, Kirby and Spence).

This is the last of the three thoracic segments (or the second of the *thorax* of Strauss, or *Alitrunk* of Kirby and Spence), and bears the posterior pair of wings, or their representatives, and the third pair of legs. Its development and consistence are variable, dependent upon the same principles, already stated to regulate the development of the mesothorax. It consists of the same number of pieces as the preceding segment, the dorsal pieces (composing the metanotum) being the præscutum (mesophragma of Kirby and Spence in *Coleoptera*; postdorsulum of the same authors in *Hymenoptera*), scutum (postdorsulum of Kirby in *Coleoptera*), scutellum (postscutellum and postfrænum of Kirby), and postscutellum (metaphragma, Kirby and Spence). The scutum and scutellum are the most conspicuous parts in *Coleoptera*, being channelled longitudinally. In *Hymenoptera*, see fig. 124, T 3, the mesothorax is reduced in size, and this is more especially the case in *Diptera*, see fig. 126, T 3; but in the parasitic *Strepsiptera*, the forewings are very minute and twisted appendages, and the second pair of wings of very large size, the metathorax being so greatly increased in its dimensions that it may be almost said to constitute the entire thorax.

The under surface of the mesothorax, or the metasternum, is generally a horny covering, divisible, like the metasternum, into various pieces; of these the central metasternum is generally the most enlarged portion; sometimes being produced into a point extending beneath the abdomen, as in *Hydrous*; sometimes it is flat, and occupies nearly the entire under surface of the metathorax; at other times, as in *Dyticus*, the posterior coxæ or basal parts of the hind legs (which are of a large size), are soldered to it, and hence the points of these parts of the hind legs have been often termed the bifid mucro of the metasternum. The sides of this metasternum in the *Coleoptera* are laterally margined by a pair of longitudinal pieces, which are the episterna, or the parapleura, of Kirby and Spence. The construction of the various parts of which the metasternum is composed would require too much minute description to be available in a work like the present; we shall therefore only further notice, that in winged insects having a pedunculated abdomen, Messrs. Audouin and Latreille consider that the piece which terminates the thorax behind is not a portion of the metathorax, but, on the contrary, is the basal segment of the abdomen. This opinion appears to us to have been successfully refuted by MacLeay and Burmeister.

The appendages of the metathorax are the posterior pair of wings, or their analogous organs, the third pair of legs, and the metathoracic spiracle.

It still remains to notice a curious apparatus, consisting of a ligament, which passes through a slit at the extremity of the postscutellum in the pedunculated *Hymenoptera*, (see fig. 124, 125, *x x*), in the middle of which is an elevation of a horseshoe form, having two apparent and one real central apertures. This ligament

\* Mr. Newman says, "In all descriptions of *Coleoptera* the mesothorax is termed scutellum." If he had said that in all descriptions of *Coleoptera*, the scutellum is the only part of the mesothorax (or rather of the mesonotum) which is noticed, he would not have misled his readers.

termed by Kirby and Spence the Funiculus, and is serviceable in elevating or depressing the abdomen.

We will now proceed to the description of the *Organs of Locomotion*; these are either wings, or their representatives, or legs.

#### 1. *Wings*, or the organs of aerial progression.

These organs, unlike the wings of birds, consist simply of a double membrane, of a very slender and generally transparent consistence, inclosing numerous nervures or veins of a firmer substance. These nervures are a kind of solid tubes inclosing the tracheæ, or aëriferous vessels in their interior, of which we have already spoken in our account of the escape of the perfect insect from the pupa skin.

These organs undergo very great modifications of form and structure in the different orders of insects; their number is also liable to corresponding variations; we say corresponding, because as one pair of wings is sometimes so completely modified as to be no longer serviceable as an organ of flight, the number of these wings is necessarily reduced from four to two. These modifications occur either in the anterior or posterior pair of wings: thus, in the *Coleoptera*, the fore-wings, although ample, are transformed into a pair of scales serving for the defence of the wings, and unserviceable as instruments of flight. The same occurs in a greater degree in the *Strepsiptera*. In the *Hemiptera* (*Heteroptera*), the four wings are of a leathery structure at the base, but are membranous at the tip; whilst in the homopterous *Hemiptera*, and *Orthoptera*, the upper wings are of a membranous nature, but much thicker than the lower wings throughout. In the *Hymenoptera*, *Neuroptera*, and *Lepidoptera*, all the wings are equally membranous. In the *Diptera* the fore-wings are alone to be found as organs of flight, the posterior wings being reduced to a pair of slender knobbed filaments. There are many cases in which the wings are totally wanting, as in the glow-worm, many *Orthoptera* and *Hemiptera*, &c.; but these are to be accounted only as casual exceptions. The same may be said of many beetles, which have the elytra, or upper wings, soldered together; in which case, as wings would be useless, they are not given to the insect.

The only recorded instance in which the posterior pair of wings have been ascertained to be developed, without there being the least rudiment of the anterior pair, is found in *Perlomorpha hieroglyphica* of Curtis, one of the spectre insects (*Phasmidæ*); also described in the last number of the Zoological Journal, under the name of *Aschiphasma annulipes*.

The wings arise respectively from the anterior lateral angles of the meso- and metathorax, articulating with the scutum and episternum, that is, just at the place where the dorsal plates of the meso- and metanotum unite with the lateral plates of the meso- and metasternum.

With respect to their consistence, the organs of flight may be divided thus:—

- a. Membranaceous wings.
- b. Tegmina.
- c. Hemelytra.
- d. Elytra.
- e. Halteres.
- f. Pseudhalteres.

a. *Membranaceous wings*.—It is by means of these membranous appendage, that flight is chiefly effected, the other variations of these organs serving more especially as organs of defence to the true wings. In

their most simple form, as in some of the minute *Hymenoptera*, especially the genus *Psilus* (fig. 128), the

wing consists but of the two layers of membrane, without any visible air-tubes, or nerves, which, in the more advanced structure of the wing, are developed, dividing it into more or less numerous divisions, like the frames of a window. This formation is more and more complete, and the divisions more and more numerous, until we find the wing exhibiting a net work of meshes too numerous to be counted; this is the case with the dragon-fly (fig. 129). In the *Hymenoptera*, and *Diptera*, the wings are essentially similar in the construction; but the nervures, especially of the posterior wings of the former, are less numerous, forming but few spaces, or cells, as they are termed. The second wings of the *Hymenoptera* are smaller than the anterior, whilst in the dragon-flies, and some other neuropterous insects, they are of equal size. If, therefore, we regard the development of wings as the chief characteristic of the *Ptilota*, or winged insects: those species which exhibit the wings of equal consistence and size, must be regarded as the types of the tribe.

The external margin of the posterior wings exhibits, also, in many insects with naked wings, minute hooks for retaining the wings on each side together during flight. These are especially found in the *Hymenoptera*, and are called hamuli. In the lepidopterous insects another structure prevails for the like purpose; the margin of the posterior wing being furnished at its base with a long and curved bristle, which is received into a little hook on the under surface of the anterior wings, in which it plays. The wings in this same order, offer another peculiarity, since, instead of being naked and transparent, they are clothed with a double layer of minute scales, somewhat resembling those with which fishes are covered. These scales, upon which the beauty of lepidopterous insects so entirely depends, are easily detached in the form of a fine dust, which, when examined with the

Feather-scales from the Goat-moth.

microscope, are exceedingly variable in their form, but generally more or less wedge-shaped, or oval; sometimes toothed, or notched, at the broadest end, some having a slender footstalk. The membranous

surface of the wing itself exhibits the appearance, when similarly examined, of numerous minute impressions arranged in lines, in which the base of the scales are planted, being laid upon each other like the tiles on the roof of a house. The derivation of the name of the order *Lepidoptera* (scaly wings), expresses this character. It has been suggested that the form of these scales might be serviceably employed in furnishing specific characters, for the determination of the various species of lepidopterous insects; but this is quite impossible, since scales of every possible form are found upon a single individual, as may be seen from the preceding figures, all of which represent scales from the goat moths.

Here it will be serviceable to notice a few of the more characteristic variations which occur in the markings of the wings of lepidopterous insects (see fig. 134): these are,

Spots (*Maculae*), which are patches of one colour appearing on the differently coloured wings (134. *a a*).

Dots (*Atomi*), which are very minute points of a different colour; when scattered over the entire surface of the wings they are said to be irrorate (*b*).

Puncta, gutta, pustula, and plaga, are words used for spots of various sizes.

Lines (*Lineæ*), narrow, generally straight marks of different colour (*c*).

Streaks (*Strigæ*), somewhat broader lines, generally transverse (*d*).

Bands (*Fasciæ*), broad transverse marks (*e*).

Vitta is a longitudinal fascia.

The four last terms are said to be undulated when alternately curved like waves (*f*), and dentated when toothed (*g*).

Annulets (*Annuli*), ring-like marks (*h*).

Imaginary wing of a Butterfly.

Eyelets (*Ocelli*), circular spots upon a differently coloured wing, with the centre also differently coloured (*i*); the latter is termed the pupil (*pupilla*), and is surrounded by the iris.

Lunulets (*Lunulae*), crescent-shaped marks (*k*).

Adjectives derived from these words are employed in describing lepidopterous and other insects. Thus we have such words as maculated, fasciated, ocellated, &c.

In the caddice flies, the wings are clothed with fine hairs, whence the name of the order given to them by Kirby, *Trichoptera*; the wings of the gnat are also beautifully ornamented with scales along the nerves of the wing. These organs, in a general sense, are of an elongated triangular form, the longest side being the exterior, or anterior, margin; the opposite angle is the posterior, or internal, angle; the side between the base of the wing and this angle, is the basal margin; or, in the posterior wings, the anal margin; the

other side is named the apical, or terminal, margin. There is, however, the greatest diversity in the shape of the wings, especially the posterior pair in the *Lepidoptera*; some are notched, and many terminated by one or more long tails. A small group of moths have been termed *Plumes*, from the wings being divided into numerous feathers, the divisions extending to the base of the wing; some are five-plumed, and others twenty-plumed.

Adjoining the external margin of the wings, at some distance beyond their middle, a callous point is to be observed, formed by the union of the nervures of this anterior or costal margin, which is termed the stigma.

In our article *HYMENOPTERA*, we have noticed more particularly the formation of the cells, originating in the nervures arising from the stigma, and which have been much employed in distinguishing the various groups of insects. That it is, in certain families highly important, cannot be doubted; but we must not rely implicitly upon it as an absolute character, since many groups, having very different habits, and varying in other important characters, are identical in the neururation of their wings. The credit of having selected these variations in the form of the cells, as affording good generic characters, has ordinarily been given to Jurine, a celebrated Swiss entomologist, who arranged the *Hymenoptera* in accordance therewith. Frisch, however, a German, and Harris, an English author, had long previously made use of the same characters.

In general, membranous wings remain expanded at all times to their full extent, but this is by no means a constant character. Thus in the *Hymenoptera*, the family of the wasps (*Vespidæ*), and the species of the genus *Leucospis*, they are folded throughout their whole length when unemployed. In the *Lepidoptera* the same occurs in the family of the *Plume* moths, already mentioned. The lower wings of orthopterous and homopterous insects, are also longitudinally folded beneath the wing covers; and the wings of coleopterous insects, are folded both longitudinally and transversely when unemployed. The posterior wings of the *Earwig* are similarly folded, the nervures, when the wings are extended, forming a most beautiful object. The position of the wings when shut, afforded to Linnæus the chief character by which he divided the moths into various sections. Thus they were said to be depressed, deflexed, horizontal, extended, divaricate, &c.

Some lepidopterous insects appear to have six wings, and have since been specifically named *Hexapterata*, &c., forming the genus *Lobophora* of Curtis; a name indicative of the real character of the wings, of which the posterior pair are furnished with a large membranous lobe.

It still remains for us to mention a small membranous appendage connected with the base of the wings in the majority of dipterous insects, to which the name of alula, or winglet, is generally given, consisting of two concave and convex membranes united together, and surrounded by a fine fringe, which fold over each other like the valves of a bivalve shell, and upon which we have seen the halteres act, in a manner similar to a drumstick beating on a drum. Kirby and Spence regard them as analogous to the posterior wings; but they are decidedly parts of, and connected with, the large wings. Somewhat similar organs have been noticed in the large water beetle,

*Dyticus marginalis*; we have also found them equally developed in the *Hydrous piceus*, at the base of the elytra.

b. *The Tegmina*.—This term was proposed by Illiger to designate that variation of wings, in which the substance is intermediate between the true membranous wings and the hard coriaceous elytra. To the substance of which these kinds of wings are composed, Kirby and Spence gave the name of pergameneous, as somewhat resembling parchment, or vellum; and the *Orthoptera* and *Homoptera* are the only insects which exhibit this kind of wing, or rather wing-cover, since the posterior wings in these orders are membranous. From elytra, the possession of very numerous nervures sufficiently distinguishes the tegmina, whilst their thickened substance equally separates them from the membranous wings. Tegmina are also distinguished from elytra by the inner edges, or anal are as folding over each other, instead of meeting in a line down the back (see fig. 130, tegmina of a *Blatta*). Like many (or rather theoretically all) membranous wings, tegmina are divisible into three areas, separated from each other by strong longitudinal nerves; the external or costal, the intermediate, discoidal, or apical, and the anal. The position in which these organs are placed in repose, varies according to the form of the body. Thus in flat insects they are horizontal, but in thick or compressed insects they are deflexed at the sides, sometimes at a considerable angle. We have seen, that in insects having the mesothoracic scutellum very prominent, the anterior organs of flight are more or less horny, and of very little service in locomotion, requiring some kind of support, which is afforded by the scutellum. They are thus circumstanced in beetles, and in the heteropterous *Hemiptera*; but in the tribes in which tegmina are present the scutellum is not a prominent organ; they are therefore more essentially organs of flight than elytra or hemelytra, which we now proceed to describe; commencing with the former, as being intermediate in their formation between tegmina and elytra.

c. *The Hemelytra* (see fig. 131, 132, hemelytron of *Heterogaster urticae*).—Under this name, Latreille described (Hist. Nat. Crust. &c. ii. p. 164) the anterior organs of flight of the *Cimicidæ*, or heteropterous *Hemiptera*, the basal portion of which is thick, opaque, and coriaceous; and the terminal part thin and membranous; the transition between the two kinds of membrane not being gradual, but sudden. The wings covered by these limbs are membranous, and of the size of the hemelytra. On examining an hemelytron, the three areas of which wings and tegmina are composed are here distinct; but they do not extend beyond the corium (or basal coriaceous part); hence the apical membrane seems a piece added to the ordinary structure; sometimes being, in fact, absent, although the corium is distinct. In some instances, the entire hemelytra are formed of membrane, or rather the substance of the corium is so much diminished that it resembles the apical membrane. When at rest, the apical membrane of one hemelytron folds upon that of the other, and the position is usually horizontal. As to their neurulation, the basal corium, as may be conceived from its similarity to the substance of the elytra, is generally almost destitute of nerves; but the apical membrane differs in having more or less numerous nerves, which serve for the distinctions of genera and sub-genera.

d. *Elytra* (see fig. 133).—This is the name given to the hard scaly or horny wing covers, or anterior wings of beetles; they are thickened opaque plates, generally carried, when the insect is not on the wing, in a horizontal position upon the back, with the internal (or anal) margin (or suture, as it is technically termed) straight, and in the direction of the middle line of the body. They are destitute of nerves, and are internally lined with a thin membrane. As to their consistence, they are variable, although generally very hard and horny; sometimes even so firm as to be with difficulty pierced by a pin. In other instances, however, they are flexible, or elastic, yielding to pressure; and in others, even soft, varying according to the variations in the consistence of the body. As to their form, they are generally in the figure of an oblong square, having the posterior angles more or less rounded; at other times they are more triangular, oval, or even almost semi-hemispheric. Sometimes they entirely cover the abdomen, at others they leave the extremity of this part exposed; and sometimes, as in the *Brachelytra*, they are very short. As to their surface, they are flat, convex, gibbose. They are also variable as regards their clothing; some being quite naked, others hairy, woolly, silky, spiny, squamose, and rugose, like shagreen, or with impressed or elevated spots, either placed irregularly (fig. 133, o), or disposed in lines (*Lineato-punctate*, fig. 133, x), or with impressed lines (*Elytra striata*, fig. 133, †). Their colours are very variable, according to the habitation of the insect. Thus beetles, living in dark places, underground, and stones, &c., are generally black, whilst those which are exposed to the light are more variegated in their tints. As already observed, these organs, during flight, are but little serviceable as locomotive instruments; and unless it were for the manner in which they are carried at such times, it must be evident that, from their size and substance, they would necessarily present a great obstacle against quick motion in the air; but this is provided against by their being carried either in a horizontal direction, where they are extended laterally, or in a vertical position, where they do not extend laterally (as in the burying beetles, *Necrophagus*). Ordinarily, as their name imports, they cover the wings; but in some beetles the wings are not thus defended, owing to the small or irregular form of the wing-covers. In the *Brachelytra*, however, in which the elytra are of the least size, and the wings large, they possess their ordinary function, the wings being very much folded. In some beetles the wings are entirely wanting; and here the elytra are firmly soldered together, thus becoming a defence for the abdomen, the upper surface of which is, in such cases, soft and membranous.

e. *Halteres* (see fig. 126 and 127, z, z).—These organs, which are usually termed balancers or poisers, are a pair of short threads arising behind the base of each of the wings in the *Diptera* (to which order they are exclusively confined), and terminated by a small oval or triangular knob. These organs are capable of a very rapid motion; and it has been usually supposed that by their beating upon the winglets (alulæ), they produce the humming noise so distinctly heard in this group of insects during flight. That they do thus beat upon the winglets, we have already observed; but it appears doubtful whether this action be the cause of the sound in question, because those *Diptera* which do not, either by nature or artificially,

possess winglets, make a buzzing noise. The same is also the case with the bees and other *Hymenoptera*. Other naturalists have supposed the noise to originate in the motion of the wings themselves, or (with more probability) in the rushing of the air through a spiracle near the base of the halteres; in which case, the sole use of the halteres will be as poisers to keep the body steady in flight. Thus Schelver cut off the halteres from a fly, and found that it could no longer fly; hence (and from other circumstances) he considered that the halteres are connected with respiration. For this reason, apparently, Kirby and Spence have regarded these organs as not being the analogues of the lower pair of wings, but as organs, *per se*, an opinion likewise maintained by Latreille (*Cours. d'Entomol.* 241. \*). Their insertion upon the metathorax, in a position with reference to the metathoracic spiracle analogous to that of the lower wings of *Hymenoptera*, together with their occurrence, in an order where only two mesothoracic wings are developed, are reasons amply sufficient to induce us (regard being especially had to the law of relative and proportionate development already alluded to, in speaking of the variation in the size of the thoracic segments) to consider the halteres as analogous to the second pair of wings, and not as anomalous appendages.

f. *Pseudhalteres* (præhalteres, Latreille).—We have applied this name to a pair of organs somewhat similar in their construction to the halteres, but placed in front of the wings, in the order *Strepsiptera*, a name signifying twisted wings, and proposed by Mr. Kirby for the extraordinary group of bee and wasp parasites; in allusion to this pair of narrow, elongated, curved, and channelled processes, which (notwithstanding the observation of Mr. F. Bauer, that they were connected with the fore-legs,) he regarded as analogous to elytra. Subsequent authors, however, doubted this analogy, and Latreille changed the name of the order to *Rhipiptera*. More recent observations have, however, demonstrated that these organs are attached to the mesothorax, which, as well as the prothorax, are extremely short; and that the large pair of fan-shaped wings are representatives of the lower wings of the *Orthoptera*, which are folded longitudinally in a similar manner, although the structure of the thorax is very different. Latreille, however, regards these organs as analogous to the mesothoracic tegulæ, or basal wing-covers, of the *Lepidoptera*. He likewise considers them as somewhat analogous to the lateral prolongation of the prothorax, observed in some species of *Psychoda* and *Scenopinus* (*Dipterous* genera). As already observed, however, they have been demonstrated to be the only mesothoracic appendages found to exist in these insects (the wings being metathoracic), consequently they must be regarded as analogous of the mesothoracic organs of flight. During the short time that these insects pass in the winged state, the pseudhalteres are observed to quiver very intensely.

2. *Legs, or the organs of terrestrial or aquatic progression*.—If we have found the organs of flight constructed in a manner totally unlike those of birds, we shall discover equally great differences in the construction of their legs. Thus, whilst the former are provided with but a pair of organs for progression on

the land, winged insects have three pairs, spiders four pairs, crabs five pairs, and centipedes and millipedes

more than a hundred legs. These organs arise from the sternum of the various segments of the thorax in the true insects, and are employed not only in walking, running, creeping, and climbing, but also in leaping and swimming, as well as in various operations connected with their economy. They consist of a series of tubular joints, formed of a similar substance with the remainder of the external parts of the body, and are provided with internal muscles and nerves. The joints have received a series of names analogous to those of the legs of the higher animals. They are the coxa, trochanter, femur, tibia, and tarsus. The coxa (136, a) is the basal joint articulating with the sternum, and very variable in form. The trochanter (136, b) is a very small piece connecting the preceding with the thigh or femur (136, c), which in general is the thickest part of the leg, and in leaping insects greatly thickened, and sometimes toothed beneath. The next piece is the shank or tibia (136, d), a piece generally somewhat shorter and more slender than the femur, and often gradually thickened towards the tip, where it is armed with one or two spurs or spines (calcaria, 136, 138, dd), varying in their number and size in adjacent groups. The terminal part of the leg is termed the tarsus (136, e), divided into several joints, never exceeding five in number, which is always found in the majority of insects with membranous wings, undefended by wing-cases. In many beetles the number is variable, as stated in our article COLEOPTERA, and the same is the case in the *Neuroptera*, &c. The under surface of these tarsal joints is generally clothed with short hair or down, often forming a kind of cushion or brush; sometimes, also, the underside exhibits several small circular membranous plates or soles (fig. 139, fore tarsus of a *Dytiscus*). The penultimate joint is also often divided into two lobes, and the terminal joint is also generally terminated by two small bent hooks (ungues, 136, f), between which, in many insects, there are one, two, or three small, often membranaceous, appendages, termed pulvilli (fig. 141, 142, 143, zzz). In some tetramerous coleopterous insects the penultimate joint is very minute (fig. 140). Messrs. Kirby and Spence regard the fore-legs of insects as arms rather than legs, and accordingly term the anterior tarsus the hand, calling the basal joint the planta or palm. That the fore-legs are highly important in performing the economy of the insect cannot be doubted; they are also often of a very different

\* Latreille consequently also regards the winglets as the true analogues of the lower wings, although he admits that "ils me semblent néanmoins partir d'un point un peu plus élevé que les ailes."

form in the individuals of different sexes of the same species. They are often formed for seizing the prey of the insect, and are then called raptorial (*pedes raptorii*), the thigh being thickened and spined, and the tibia closing upon it. The hind legs are also often peculiarly organised, as in the bees, where they are polliniferous (*pedes polliniferi*), or in the grasshoppers, &c., where the femora are greatly thickened, and used in leaping (*pedes saltatorii*, fig. 137)\*. In some other insects they are terminated by a broad, flattened, and strong ciliated tarsus, admirably formed for swimming, as in the water-beetles (*pedes natatorii*, fig. 138). The tibia in the anterior legs are often dilated and notched on the outer edge, as in the mole-cricket. These legs thus become proper for burrowing (*pedes fossorii*. See our article ENTOMOLOGY for figures of these variations of legs). In some lepidopterous insects, especially amongst the butterflies belonging to the family *Nymphalidæ*, the fore-legs are very short and rudimental, the tarsi being almost obliterated, and quite unfitted for walking. In some insects the various parts of the leg fold upon each other when unemployed, and are there received into certain channels prepared for their reception on the under side of the thorax. This is the case with the pill-beetles (*Byrrhidae*), mimic-beetles (*Histeridae*), &c. As regards the relative proportions of the legs of insects, the general rule is, that the anterior are the shortest, and the posterior the longest; and as regards their length, the shorter and more robust the body, the shorter are the legs, and *vice versâ*. In running insects, also, the legs are longer than in those which crawl. Generally, the legs do not much exceed the body in length, but occasionally they are much longer. As regards their direction, the anterior legs are generally directed forwards, and the four posterior backwards. It would occupy far too much space were we to enter into a detailed notice of all the variations in form which occur in the legs of insects.

C *The abdomen, or the seat of the organs of generation.*—We have now arrived at the third and last principal division of the body which encloses the greater portion of the intestines, the organs of generation, and their appendages. Unlike the preceding part of the body, the abdomen, from being destitute of locomotive organs, necessarily exhibits a much less complicated organisation in the various segments of which it is composed than those of the thorax, and typically consists of nine segments, exclusive of the anal apparatus, each being composed of two arcs, or half segments, one upper and the other under. These rings are attached together by membrane, and either meet at the edges, or slide into each other like the tubes of a telescope. The dorsal one is termed the back (*dorsum*), and the ventral one the belly (*venter*). We have already seen that, in the larva state, several segments exist which are not found in the imago; and the examination of the abdomen in various insects clearly proves that these last segments are abdominal ones. Thus, if a male ear-wig be examined, it will be perceived that there are nine distinct abdominal segments, exclusive of the anal forceps; but in the female, it will be perceived, that although, with great care, the nine segments be discoverable, two of the terminal ones have assumed a rudimental appearance.

The abdomen of some beetles exhibits a curious character in this respect. Thus, in *Carabus*, if the under surface of the abdomen be only examined, it would appear that there are but five abdominal segments; but, if the back of this part be viewed, nine joints will be discovered; another peculiarity exists in the stinging *Hymenoptera*, in which the males have seven, and the females only six abdominal segments. The union of the abdomen with the thorax is effected in two different modes in different groups. Thus, in all insects which have the wings defended by wing-covers *hemelytra*, *octegina*, (beetles, bugs, tree-hoppers, &c.), as well as in many insects with entirely membranous wings, the base of the abdomen is as large as the extremity of the metathorax, and is united to it by membrane throughout its entire breadth or circumference, in which case the abdomen is said to be sessile. In the hymenopterous order, the saw-flies and *Siricidae* are distinguished by this character from the other tribes. In the other mode, the abdomen is connected with the thorax only by a slender portion of its base, and this is the case with those insects to which we have alluded in our account of the curious apparatus for elevating the abdomen, in our account of the metathorax. Insects thus distinguished are divisible into two sections; first, those in which the union is effected by a very short piece, and the abdomen is as broad as the posterior part of the thorax, so that, as in the hairy-bodied bees, it appears to be affixed by its entire breadth; and, second, those in which the connecting piece is elongated into a peduncle, and the base of the abdomen itself narrow. This is the case with many exotic wasps, and wasps (*Ammophila*), &c. In the latter division the abdomen is said to be pedunculated or petiolated. The peduncle itself is liable to great variation. Thus, in some ants, it consists of two knots (*petilus binodosus*); in others only of one. Sometimes it is disproportionately long; at other times it is saucer-shaped, bell-shaped, &c. Of the shape of the entire abdomen little in general can be said. It is, however, more generally triangular, ovate, or quadrate, with the posterior angles rounded off; generally, too, the upper surface is more or less depressed; sometimes it is very short, at others disproportionately long; sometimes wider than the thorax, but more commonly narrowed. The extremity of the abdomen is generally pierced by the anal aperture. The terminal segment is very variable in its form, being formed with reference to the coupling of the insects, or to facilitate the disposition of the eggs in appropriate situations. Sometimes, also, it is organised in a manner to become an instrument of defence or offence. The various organs to be noticed below form part of this segment. It still remains for us to notice the motions of this part of the body. Unlike the thoracic segments, which, from bearing the organs of locomotion, are necessarily required to be as firm as possible, and are not, consequently, capable of much distinct motion, the abdominal segments being destitute of such organs, and having important functions to perform, are, on the contrary, gifted with a considerable but variable degree of motion. Thus, in those species which have the extremity of this part of the body furnished with offensive or defensive instruments, it is capable of very considerable movements in every direction. This is the more noticeable in insects which have a very much elongated abdomen; as, for instance, the ear-wig,

\* We must refer to the article CEROPIDEÆ, where we have entered into various details relative to this subject.

the *Staphylinidæ*, &c.: Insects which, on the contrary, have the abdomen short, and especially those in which it is defended by the wing-covers, possess but very little power of motion in this part of the body. Another circumstance, also, has much influence in the same respect; when the segments of the abdomen simply touch each other at the margins, the motion is very limited; but in those which have the abdominal wings formed to slide into each other, the motion is much more extensive.

The organs of generation (with the exception of those of the male, *Libellulæ*, which are placed beneath the first abdominal segment), are situated at the extremity of the abdomen.

The sting (*aculeus*), and the ovipositor (*oviductus*), are the only instruments connected with these organs which it will be convenient to notice in a work like the present, and these have already been described in our articles, *Hymenoptera*, *Cicada*, &c. Besides these, the extremity of the abdomen is sometimes furnished with additional appendages, such as the forceps of the earwig, common to both sexes (but considerably larger in male than the female), and of the scorpion-fly (*Panorpa*), in which it is only found in the male: the long and slender threads of the may-flies (*Ephemera*), which seem to be of service to these insects in their alternate rising and falling flight, being brought into contact when ascending, but expanded during the descent; other shorter and broader appendages are found in the dragon-flies, cockroaches, spectre-insects, &c., sometimes these appendages are articulated, at others simple and entire.

We have now brought our review of the external organisation of insects to a close. That it has extended to a considerable length we are aware, and that it must be to a certain extent comparatively uninteresting to many readers we much fear; but it appeared impossible to dismiss the subject at shorter length, consistent with the increased number of organs exhibited to us by insects, and which so far exceed those of the higher animals. We have endeavoured as far as possible to keep clear of those minute details which may be said to have reference to a specific instead of a general sketch of entomology. We have, therefore, in the next place, to direct our attention to

#### Sub-section 2.—The internal anatomy of insects.

Having already stated that the skeleton (upon the variations of which much importance is placed in the higher animals), is in insects external, we at once perceive that our labours on arriving at the internal anatomy of the latter have considerably diminished.

This, indeed, is one of the chief charms of this branch of zoology; for whilst in the other invertebrated animals it is almost impossible to preserve the individuals, except in spirits; and in the vertebrata, except by stuffing the skin, whereby the form of the body is entirely dependent upon the fancy of the person who "puts up" the specimen; insects in almost every instance preserve their form and colour with a freshness often quite equal to the life. It remains for us, therefore, to notice (which we shall do in the most concise manner); the internal systems of sensation, digestion, circulation, respiration, and motion. The generative system, for obvious reasons, will be left untouched by us.

A *The sensitive or nervous system*.—The chief means whereby the intercourse of animals with the external world, by the instrumentality of the senses,

is maintained, is the nervous system, originating in the brain or the spinal cord.

Hitherto this branch of our subject, and indeed the internal structure of insects in general, has received too little attention from entomologists, of whom we are compelled to say, that mere external form and the collecting of specimens occupy their chief attention. Swammerdam was the first author who carefully traced the nerves of several insects, as the bee, the silkworm, and the *Oryctes nasicornis*; but Lyonnet was far more elaborate in performing the same operation in the caterpillar of the goat-moth. More recently Strauss-Durckheim, L. Dufour, and Burmeister, and especially, with reference to its gradational modification at various periods, M. Herold in the white butterfly, and our own countryman, Newport, in the *Privet Sphinx*, have laboured assiduously in the same field.

Nervous system of the Caterpillar of the *Cosmus ligniperda*. The dotted lines indicate the situation of the nerves concealed by the incumbent muscles.

In insects, as in the other articulated animals, this system is quite unlike that of the higher animals, and consists of two medullary cords or threads, exhibiting a series of knots or ganglia, whereby they are united together at certain distances, occupying the lower surface of the internal part of the body, and being defended from the action of the thoracic sternums by the internal Y-like processes above described, as the pro-, meso-, and metathoracic furcæ. Sometimes the two ganglia of each segment are more or less distinct, and sometimes they are united together side by side, occupying the medial line of the body; and the same occasionally occurs with the communicating threads themselves. The nervous ganglia or knots are placed at more or less equal distances from each other throughout the entire length of the insect, sometimes, indeed, so close, that they constitute but two or more ganglia.

This is the case in the perfect state of the hemipterous insect, *Ranatra linearis*, for a figure of which the writer is personally indebted to John Anderson,

Nervous system of *Ranatra linearis*.

Esq., of Richmond, by whom a most elaborate series of preparations of the nervous system throughout the entire range of the animal kingdom has been made, in illustration of a very valuable paper read on the 23rd of April last before the Physical Section at Guy's Hospital, with reference to the remarkable analogies (noticed in the early part of this article), exhibited by the human embryo in the various stages of its passage to perfection, with the perfect state of the inferior animals. We trust that this admirable memoir will be shortly published.

In the larva there are thirteen knots, corresponding with the number of rings of the body; but these organs, like the other internal systems, are modified during the passage to the perfect state. Thus Dr. Herold in his celebrated work upon the Internal Anatomy of the white Garden Butterfly, ascertained as the larva approached maturity, the second ganglion became united with the first; the fifth and sixth approach and unite; then the third and fourth; whilst in the pupa, the seventh and eighth have entirely disappeared; so that, instead of thirteen, the imago possesses but eight ganglia.

On examining the invertebrate, or rather the externally vertebrate structure of an insect with that of the internally vertebrate animals, we find no part corresponding with the brain; or rather the organ which might be regarded as analogous thereto, and which, indeed, has been called the brain, namely, the ganglia of the head, are repeatedly represented along the entire length of the body; consequently it has been supposed that the nervous cord of the insect represents the great sympathetic nerve of the latter; although, perhaps, it would be more correct to regard it rather as the spinal cord.

The matter of which the nerves are composed is a soft pulpy substance, enclosed in a simple and transparent membrane.

The first pair of ganglia is always situated in the head of insects above the digestive canal, and is furnished with nerves extending to the eyes, antennæ, mandibles, maxillæ, and labrum. The other ganglia

are lodged in the thorax and abdomen, or in the former alone, and similarly placed above the alimentary canal; the two thick nervous filaments connecting the head ganglia with the prothoracic ganglia are deflexed, so as to surround the oesophagus, forming a kind of nervous collar. From the thoracic and abdominal ganglia are emitted nerves which communicate with the legs, wings, and other organs of the body. In the larva of the goat-moth, Lyonnet counted forty-five pairs of these nerves, besides two single ones, thus making a total of ninety-two, which is considerably more than are found in the human body; namely, seventy-eight.

In the vertebrate animals the nerves proceed from the brain, which is enclosed in the head; in insects, on the contrary, we have seen that nerves proceed from the various knots, whether belonging to the head, thorax, or abdomen; hence we might analogically call the various ganglia and their connecting filaments an elongated brain. In the vertebrate animals sensation originates in the brain; and hence, from the concentration of this organ into one mass (for so we may call it although divided into two lobes), sensation is more concentrated, and the feelings rendered highly acute. In insects, on the contrary, owing to the want of concentration of the nervous ganglia, sensation is necessarily much less acute; and, as the nerves laterally emitted by one ganglion generally serve for the segment of which it forms a part, the connexion with the preceding or subsequent ganglia being at the same time slight in proportion to the slowness of the connecting filaments, we are enabled satisfactorily to account for the apparent want of sensation in insects, as exhibited, for instance, in the cockchafer, which will walk about, although some bird has nearly emptied the body of its viscera; or by the head or abdomen of a wasp, which will continue to bite and sting long after they have been separated from the rest of the body; or by the headless trunk of a male mantis, which has been known to unite itself to the other sex, as recorded by Dr. Smith, and quoted by Kirby and Spence. Another instance is recorded by the Rev. Mr. Bird, in a memoir published in the Entomological Magazine, entitled, "On the want of Analogy between the Sensations of Insects and our own."—"When I was young in entomology," observes this kindly-hearted writer, "I wished anxiously to find the quickest mode of killing an insect. Having captured a pretty beetle, *Malachius ceneus*, it struck me that by cutting it in two at the junction of the thorax and abdomen, the part which gives rise to the name insect, *Insectum*, *Εντομον*, I should kill it in a moment. I took a pair of scissors and divided it; the parts fell on a piece of white paper which lay before me. Far from being dead in an instant, I was grieved and surprised to see the head with the two fore-legs attached to it begin to run about the paper. It occasionally stumbled, but rose again, and exhibited, if I may so speak, perfect self-possession. It made for the edge of the paper; but arriving there and looking over it, seemed to think it too precipitous, and so coasted along in quest of an easier descent, which, nevertheless, it did not seem able to find. This coasting and searching for a convenient place of descent, suited to its curtailed condition with respect to legs, of which it appeared perfectly aware, occupied the head incessantly. I regarded it with astonishment—Here, then," I said to myself as I watched

its motions, 'here lies the vitality of an insect; the body at any rate is dead;' but in this I was quickly undeceived, for in about a minute after the body had fallen upon the paper, I saw the hind legs brought upward, and employed in deliberately brushing and cleaning the wing-cases, exactly as a house-fly may be seen to clean its wings on a window pane. The legs were then withdrawn, the cases raised up, and true wings expanded from beneath, and all made ready for flight, which, indeed, I expected to see; but the body seeming then to become aware that there was no guide, the head, its former companion, being in possession of the eyes, the design was abandoned, the wings folded up in their usual beautiful manner, and the attitude of rest again assumed. This whole process was repeated with perfect regularity at intervals of about a minute, if I rightly remember\*. A more perfect act of a sentient creature could not be exhibited: the head continued to run about, and the body to clean and expand its wings, the one for about twelve and the other for sixteen hours, their energies gradually decaying, till they appeared to perish, or rather to sleep. And now, I ask, which was the beetle? where was the original creature? had not the head and the body an equal right to be taken as its representative? Is not all analogy between insects and ourselves destroyed by such a phenomenon?" And in the same view of the subject it has been considered better to consider each nervous ganglion as a separate and independent centre of volition. But surely we have no authority for adopting such a view, the ganglia being united together, and the insect constantly dying when thus divided, instead of each portion forming itself into a new being, like the planaria and some other invertebrated animals.

The nerves, as before observed, form the medium whereby the notice of the various transactions of the external world is conveyed to the seat of the instinctive or intellectual organs. The perceptions thus obtained constitute the senses, of which *sight, hearing, smell, taste, and touch*, are those which are generally allowed to prevail. Some physiologists (Dr. Virey, &c.), add to these *love*, and the internal sense of *thought or instinct*.

The former of these, as a perception distinct from the mere physical act of propagation, can scarcely be allowed to insects. In this point of view the subject cannot be discussed in a work like the present. The instinctive powers of insects also appear to the writer of this article to be on a very different footing compared with the other senses. We shall therefore defer our observations thereon to the subsequent section of this article.

That insects possess several of the senses is certain; but the seat of these senses is not ascertained; nei-

ther can we by any possibility arrive at a certain conclusion that the senses of these animals are identical with our own. Their entire organisation having been shown to be so totally different from that of the vertebrated animals; indeed, as Mr. Mac Leay has observed in the *Horæ Entomologicæ*, there is no reason why animals constituted upon a plan so totally unlike our own, should not possess senses of which we have no idea. We will, however, adopt the general opinion, and speak of the senses of insects as analogous to our own, the consideration of which will form so many distinct sub-sections.

a. *The Sense of Sight*.—The eyes of insects are the only organs which we can with any certainty refer to the sense of which they are the seat. We have already described the external structure of the eyes, and ocelli or eyelets, and shall therefore now notice their internal organisation, and the mode in which vision is effected. On making a perpendicular incision into the eye, it is found to consist of various layers; the external membrane is hard, transparent, and composed of a multitude of hexagonal facets, each forming a more or less distinct conical cylinder, running towards the centre of the eye; beneath this external membrane is a layer of coloured matter, often of a blackish violet hue, but sometimes green, red, or banded, pierced with as many holes as there are facets or pupils; beneath this is a varnish of a black colour, within which is another belt, the inclosed space receiving the optic nerve, with its numberless ramifications, a branch probably going to each facet. The structure and functions of the eyes of insects have been investigated with great accuracy by Müller, who has proved that the refractive powers of the ocelli must be very great, each ray of light suffering a four-fold refraction; the first produced by the convex cornea, the second by the anterior convex surface of the lens, the third by the posterior convex surface of the lens, and the fourth by the convex surface of the glassy body itself; hence a very distinct short sight, suitable for small objects, is possessed by these eyes. In the compound eyes the effect is different, here, owing to the convexity of these eyes, and the consequent obliquity of the lateral facets and their cylinders, a much wider horizon must be embraced, each individual facet surveying but a small space of the entire field of vision, each thus contributing to the perception of objects comprised within the view, those rays of light only that fall in a right line upon a facet, which itself forms the segment of a circle, can reach the optic nerve of this facet, whereas all others are withheld by the pigment which separates the individual glass cases from each other, and partly circularly surrounds the margin of the crystalline lens beneath the cornea. According to Müller, each nervous filament conveys to the bulb of the optic nerve the impression of the ray which it has individually received; and as all the nervous filaments at first separated by the pigment are at length united together into one common and continuous bulb or nervous expansion, the impression received by each filament is united to those of the others in the bulb of the optic nerve, and so a common and continuous image is produced. This author, however, further considers, that rays coming from one point of a remote object will illuminate throughout more than a single cone, and thus to each luminous point without there will correspond in the interior of the eye, not exactly a single illuminated point, but rather a little circle of diffused or

\* This fact apparently controverts the conclusion of Burmeister, that after the separation of the nervous cord at any part, the voluntary motion of the organs seated beyond the point of incision is lost, but that the irritability of the muscles, that is to say, their power of reaction upon external excitement, is retained by these organs as long as life remains. We say apparently, because when the increased size of the muscular system of the wings in malachius (which is a strong flier), is considered just as in the swimming motion of the hind legs in a dytisc deprived of its anterior ganglia, recorded by Burmeister and in which the muscles of the hind legs are very greatly developed, the unfolding and folding of the wings may be explained, without reference to instinct supposed to be possessed by this remnant of the body.

dispersed light, and in consequence an image of but little distinctness will be reproduced on the internal surface or retina, the distinctness of the image increasing in proportion as the object approaches the eye. It is, however, admitted, that the distinctness of the image will increase in proportion to the number of facets, and the length of the cones, for the longer the cones are, the more completely will all rays entering them obliquely be prevented from reaching their internal extremity or apex. Upon these remarks we would, however, be permitted to observe, that, from the fact of each facet being the segment of a circle, as well as from the exceedingly minute size of the pupil-like aperture of the pigmental division of each facet, those rays only which fall upon the centre of each facet, and pass down the axis of each cylinder, can reach the nervous filaments in the centre of the eye, and thus there can be no such dispersion of the rays and consequent indistinctness of vision above noticed. We submit this opinion with great deference, and because it appears to us, that in the various experiments made upon this subject, due allowance has not been made for the external circularity of each facet of the cornea.

Immediately in connexion with the sense of sight ought to be noticed that remarkable property which many insects possess of emitting a peculiar light, and which, as we apprehend, should be regarded as displayed by insects with a view to its perception by the eyes of their associates, just as the chirping of a cricket is adduced in favour of the hearing of its fellows. Amongst insects, the *Lampyridæ* (or Glow-worms, which see) and the *Elateridæ* are the only families which are decidedly proved to possess this faculty; although it has been asserted to prevail in the *Fulgoridæ*, and some isolated species of other groups, but there is no distinct evidence of its existence in these latter insect. We must, however, refer to the various articles upon these families, where we have dwelt more at large upon the nature and peculiarities of these luminous exhibitions.

b. *The Sense of Hearing.*—Linnæus describes insects in general as "*Muta nisi alio proprio instrumento, sonora; Surda stridorem ætheris licet percipiant.*" From many facts, however, it is evident that insects distinguish sounds in some manner or other, although the greatest uncertainty prevails amongst naturalists as to the organ of this sense. Without presuming to offer any opinion of our own upon a point on which so many learned physiologists are at variance, we shall content ourselves with noticing the production of sounds caused by insects, which has invariably been employed as an argument in favour of the possession of the sense of hearing by these animals, and then allude to the opinions which have been entertained as to its seat.

Unlike the higher animals, insects possess no distinct vocal apparatus terminating in the mouth. The noises made by insects may be divided into three kinds, according to the mode in which they are produced. In the first, the sound is produced by the mere friction of one part of the external integument against another, whereby, when an insect is disturbed, it forcibly rubs one portion of its body against another in its endeavours to escape. In this manner, by the friction of the prothorax against the base of the mesothorax, or the abdomen against the elytra in beetles, a continuous and rather loud sound is produced. The second kind of sound is produced by numerous

flying insects, and which our bard of the Seasons has alluded to in his lines,

Yet not unpleasant is the ceaseless hum  
To him who wanders in the woods at noon.

The mode in which this sound is produced has been endeavoured to be explained in a variety of ways. We have already alluded to these opinions in our account of the *Halteres*, and shall only add, that the experiments of Burmeister and others, together with the fact that bees produce as loud a sound as dipterous insects, although unprovided, like the latter, with winglets or halteres, seem satisfactorily to prove that it is owing to the rushing of the air through the thoracic spiracles that the buzzing is produced. The third kind of sound is produced by a distinct modification of certain organs for their express emission. We have already described these structures in the Linnæan genera *Gryllus* and *Cicada*, which comprise the only insects thus circumstanced, and which are confined to the males. The death's-head moth also produces a plaintive kind of cry, as described in our article upon that insect.

In many works we find the effects of other sounds upon insects described, an instance of which we have already recorded in our account of the great green grasshopper.

As to the organs supposed to be the means whereby this sense is produced, we find that the opinions of the majority of authors may be divided into those by which the seat of this sense is asserted to be wholly unknown, and those who consider that the antennæ in some way or other perform the functions of organs of hearing. Other opinions have, indeed, been maintained by several other and distinguished authors. Thus Treviranus described a small drum-like membrane\* on the forehead in front of the base of each antennæ in moths, to which nerves extend, but no analogous organ has ever been discovered in other tribes of insects. Müller in like manner regarded part of the chirping apparatus of the grasshopper as an organ of sound; whilst Rudolphi considered the anterior salivary glands of bees as similar organs. Of continental authors who have regarded the antennæ as analogous to ears, the most celebrated are Sulzer, Scarpa, Schneider, Berkhausen, Reaumur, Bonnsdorf, Carus, Strauss-Dürkheim, Oken, and Burmeister. Kirby and Spence adopt the same view to a certain extent, considering it probable that the primary function of the antennæ may be something related to hearing; they further conceive that antennæ, by a peculiar structure, may collect notices from the atmosphere, receive pulses or vibrations, and communicate them to the sensorium, which, though not precisely to be called hearing, may answer the same purpose. It is true that the antennæ have, by other authors, been regarded as the organs of smell and of touch, the grounds for which we shall notice in our observations upon that sense. Moreover in the higher crustacea (crabs, &c.), the organs of hearing distinctly exist in the shape of oval apertures, inclosing moveable plates, and placed at the base of the larger pairs of antennæ, a circumstance which has been considered as affording a strong analogy in favour of the opinion that the antennæ are organs of hearing.

c. *The Sense of Smell.*—That insects possess, in a high degree, this sense, is evident to every one who

\* Did not Treviranus here mistake the acelli for the ears?

knows with what pertinacity the blow-fly discovers meat, even when concealed under napkins, in safes, &c. That butterflies will fly down to flowers from a considerable height, may be accounted for by the action of their eyes, indeed we have seen butterflies fluttering on the outside of windows, within which were coloured bits of paper, which they evidently mistook for flowers. In the two preceding senses we have seen that their existence might be presumed from the existence of luminous properties in certain species, or by the emission of sounds by others. In like manner the discharge of numerous and varied scents by many insects, induces us to admit the sense of scent in insects, although the organ of this sense is as little ascertained as that of hearing. Thus the disgusting odour of the bug, the cock-roach, or the lady-bird; the rose-like scent of the cicindela; the musk-like scent of the musk beetle; the garlic scent of many andrenæ; the goat-like scent of the caterpillar of the goat moth; or the strong acid smell of many of the ants, sufficiently prove a keen perception of effluvia in insects. As to the organ of this sense the majority of naturalists, Baster, Lehmann, Cuvier, Dumeril, Audouin, Strauss-Dürkheim, and to an extent Burmeister, from analogy with the vertebrated animals, regard the lining of the spiracles as exercising this function; whilst Christian, Reaumur, Lyonnet, De Blainville, and Latreille, consider the antennæ in this light. Marcel de Serres and Bonnsdorf, as well as Christian, conceive the palpi to be smelling organs. Comparetti described various cavities and cells in the front of the head, which he regarded as performing the office of a nose; but his assertions have never been confirmed. Treviranus considered the entire mucous lining of the mouth as the organ of smell; whilst Kirby and Spence give the name of rhinarium, or nostril piece, to the membrane connecting the skull and the clypeus (which they call the nose), and have described a pair of circular pulpy cushions under the clypeus and rhinarium, covered by a membrane transversely streaked with beautifully fine striæ, as the organs of smell, which they discovered in the burying-beetle (*Necrophagus vespillo*) and some others. But these discoveries are not confirmed by other and more elaborate insect anatomists, who have discovered no similar organ, nor do Kirby and Spence indicate how scents can pass through the rhinarium.

d. *The Sense of Taste*.—If we have noticed the flesh-fly, as affording a proof of the existence of scent of insects, the same insect may be again cited to prove that insects are not deficient in the sense of taste; indeed, to suppose that animals, having such a beautifully constructed and complicated oral apparatus as is exhibited by the mouths of insects, which also exhibit such discrimination and fastidiousness in the choice of their food, should be deficient in this sense, seems not to be very philosophical, although such has been asserted by Rudolphi and some other physiologists. That this sense is seated in some part of the mouth or digestive organs is, however, generally admitted. Some authors, however, have supposed it to exist in the palpi, whilst others regard it as seated in the pharynx, or at the commencement of the throat. The tongue, however, is more generally regarded as its real seat, this being a fleshy organ in many insects, and provided with a great abundance of nerves, and furnished with saliva from the mouths of the ducts of the glands lying beneath this organ. It must, however, be admitted, that there are many

insects in which the analogue of the tongue is not developed, or exists merely as a horny seta.

e. *The Sense of Touch*.—In the higher animals the outer envelope of the body is, from its peculiar construction, generally, and in all parts, adapted to receive impressions by this sense; but in insects, the hard scaly texture of the external covering necessarily prevents such a general system of touch, and we are therefore compelled to search for organs which may in an especial manner be regarded as the organs of this sense. Here, too, however, we find difficulties similar to those which have met us in our researches relative to the other senses: thus the antennæ, palpi, wings, and tarsi, and particularly the anterior tarsi, have been regarded as the organs of this sense; and, indeed, the opinion, that the first-named organs constituted the real feelers, has been maintained by some writers with so much zeal, that even violent abuse has been heaped upon persons professing a different view of the subject. It is true, that the antennæ have been generally termed feelers, and the proceedings of some of the *Ichneumonidæ* have been adduced as instances in support of these organs being capable of feeling (as detailed in our article *ICHNEUMONIDÆ*); but here, as Kirby and Spence observe, either by means of its antennæ, it hears a slight noise made by the latent grub, perhaps by the action of its mandibles, or else that, by its motions, it generates a motion in the atmosphere of its habitation, which, striking upon the antennæ of the parasitic ichneumon, are by them communicated to its sensorium. Moreover, the ovipositor of these insects is much longer (in *Fænus* and *Pimpla*) than the antennæ; so that, by inserting the latter into the holes in walls, posts, &c., it is impossible that they can reach the latent grub. Strauss-Dürkheim, and some others, on the contrary, regard the articulated tarsi as the organs of touch; Kirby and Spence considering them also as organs of *active touch*, whilst the same authors, together with Knoch, Lehmann, Cuvier, and Burmeister, regard the palpi as the organs of touch, these parts being, without intermission, applied to every surface, and being terminated by a minute transparent membrane, which is supposed to be the precise seat of this sense; although Strauss-Dürkheim, who carefully examined it, considered it as the organ of a distinct double kind of sense, partaking both of touch and taste. In some bees which we are at present experimenting upon, and which thrive upon moistened white sugar, we notice the maxillary palpi applied to the surface of the sugar all the time that the insect continues to feed.

#### B. *The Digestive System*.

After the food has been taken into the mouth and been submitted to the action of the trophi, it passes into the pharynx or entrance to the stomach. The digestive organs are opened at each end, extending from the mouth to the anus; sometimes they are straight, and at others bent or twisted together; and, as in the higher animals, they are short in the predaceous species, but elongated in those which feed upon plants: sometimes they are of an equal diameter throughout, but at other times variously constricted. Where the number of these constrictions is the greatest, the digestive tube consists of, 1st, the pharynx; 2nd, the œsophagus or gullet; 3rd, the craw or jabot; 4th, the gizzard or ventriculus; 5th, the stomach or duodenum; and 6th, the intestines,

including the *intestinum tenue* or small gut, the *cæcum* or blind gut, and the *rectum* or vent gut. In addition to this variously divided digestive tube,

it penetrated by imbibition. Strauss-Dürckheim, however, discovered that there exists in the cock-chaffer a series of orifices opening into each side of the dorsal vessel, and furnished with valves.

Figs. 146, Digestive system of *Melolontha*; 147, ditto of *Staphylinus* (from L. Dufour).

there are a number of slender membranous tubes filled with a fluid apparently analogous to the bile; they are, for the most part, inserted into the stomach near its outlet, where the secretion, which is thus discharged, acts upon the already partially dissolved food, and converts it into a pulpy mass or chyle, the nutritive parts of which, as it passes into the small gut, are taken up by the inner membrane of the latter, and passed into the cavity of the abdomen, lying upon and around the parts to be nourished by absorption. The indigestible parts of the food are collected in the *cæcum*, and thence passed out of the body.

#### C. The Circulatory System.

It has been generally considered that insects were destitute of a real and direct circulation analogous to that of the higher animals; but the recent observations of many distinguished authors (Comparetti, Carus, Bowerbank, Burmeister, &c.) appear to have fully proved that they do possess such a system. Although there is no part in insects strictly analogous to the heart, yet this name has been ordinarily given to a series of large reservoirs forming a longitudinal tube, extending throughout the entire length of the body (commencing at the first thoracic segment) beneath the dorsal integuments and muscles, and which is easily distinguished by its alternate contractions and dilatations, similar to those of the heart in the higher animals, which may be constantly observed in the silk-worm and other naked caterpillars. In this dorsal vessel, as it has been called by some physiologists, the blood is contained, and which, unlike that of the vertebrata, is cold, transparent, and often entirely colourless. It was, however, considered that as no outlet had been discovered, there could be no circulation, and yet it was supposed that the fluid in some way or other made its escape, and was disseminated amongst the various internal organs, which

Figs. 148, Larva of *Ephemera*, showing the central dorsal vessel, some of the valves being opened, the current of the fluid being indicated by arrows (from Mr. Bowerbank); 149, lateral view of the dorsal vessel of *Melolontha*.

The dorsal vessel consists, according to Strauss-Dürckheim, of eight successive chambers in the cock-chaffer. Mr. Bowerbank says "they are about equal in number to the sections of the body" in the larva of an *Ephemera*, separated by converging valves, which allow the blood to be propelled forward towards the head, but prevent its returning. The blood abounds in very minute oat-shaped particles, and is seen circulating in every part of the body, from whence, upon each pulsation and opening of the lateral apertures, it rushes into the dorsal vessel, and is conveyed into the anterior part of the body. When the terminal chamber is filled, the blood which it contains causes the lateral valves to close, and the blood to be propelled into the next chamber, which, at the same time also receives a flow of blood from its own lateral openings. In this manner the blood is forced towards the prothoracic chamber, where it terminates, according to Strauss-Dürckheim, in a single artery without branches, which carries the blood into the head, where it is poured out, and thence flows back into the cavity of the body (in distinct arteries, according to Mr. Bowerbank), to be again taken into the heart, which consists of two membranes, the external one of which is furnished with numerous ramifications of the air-tubes. The various air tubes also which are distributed throughout the body, communicate with the blood as it is discharged from the prothoracic chamber, and thus it receives as supply of oxygen. The number of chambers in an imago appears to be smaller than in a larva; we have also seen that the number of segments in the latter are more numerous than in the former. It would therefore form a very interesting subject of inquiry to ascertain the mode in which, and the period when, this loss takes place. The circulation of the blood

is most distinctly seen in the aquatic larvæ, and in the wings of insects, owing to their transparency.

#### D. The Respiratory System.

The systems of circulation and respiration are necessarily dependent upon each other. In the higher animals the lungs are the receptacles of the air, and the blood rushes into these organs to be oxygenated. In insects we have, however, seen that the circulatory system extends throughout the body, the great dorsal vessel equally extending from one end of the body to the other; hence it is requisite that the respiratory apparatus should be developed to an equivalent degree, and we accordingly find that respiration in insects is effected by means of two great longitudinal vessels or canals called tracheæ, running along the sides of the body beneath the outer integuments and muscles, and which open to the outer atmosphere by means of short tubes, terminating in breathing pores (spiracles or stigmata). The number of these spiracles

together. The composite spiracles are, on the contrary, appropriated to the thorax.

The tracheæ, which originate in the spiracles, are connected with the two great longitudinal air tubes above mentioned, which likewise emit an infinite number of ramifications extending to all parts of the body, like the branches of a tree. These tracheæ are of two sorts, tubular or vesicular: the former are tubes composed of three distinct membranes, the external and internal layers being of a cellular texture, and the central being composed of a cartilaginous thread, rolled in a spiral direction, and very elastic. The vesicular tracheæ are destitute of this spiral cartilage, and are small bags of a cellular texture, which, when not distended with air, naturally become flaccid. The tracheæ often communicate with each other, and penetrate all the organs, such as the legs, wings, &c.; they are also distributed throughout the intestinal parts of the body, so that the air circulates freely in the most obscure parts.

We have already noticed in our articles *DYTICIDÆ*, *CULICIDÆ*, *CHIRONOMUS*, *EPHEMERA*, and in the present article, various modifications exhibited by the respiratory apparatus of the insects belonging to these groups, which are chiefly aquatic, and in which we perceive two principal modifications: 1st, A series of large lateral organs which act upon the water, and abstract from it the oxygen; and, 2ndly, a concentration of the respiratory functions, by means of an apparatus placed at the extremity of the body, whereby the insect is enabled to obtain a supply of air by protruding this part of the body above the surface of the water, whilst it still remains with its greater part submerged. M. Audouin has also recently noticed another remarkable modification of the respiratory apparatus in insects, which, although terrestrial, are occasionally covered for a great length of time with water. (See his Memoir upon *Nepus fulvescens* in the *Nouvelles Annales du Muséum*).

Fig. 150, Respiratory apparatus of *Nepu cinerea*, in which the only pair of spiracles are placed at the sides of the anus, the lateral spiracles being obsolete or rudimentary.

is various; those of the larva, in which the body is composed of a more regular and uniform series of segments, being more numerous than the spiracles of the imago. In the former they amount to eighteen, that is, nine pairs; whereas, in the generality of perfect insects, the number is, or appears to be, diminished; moreover, in the latter, the spiracles, owing to the greater development of external covering, are generally more or less concealed. Spiracles are of two kinds, simple or composite. In the former the aperture is a simple orifice guarded only by hairs, which prevent the passage of any foreign substance which might be injurious; but in the composite spiracle the aperture is closed by two horny valves, which move backwards and forwards like a pair of folding doors at each inspiration. The former sort of spiracles are generally found at the sides of the abdomen, where the upper and lower arcs of each segment are united

Fig. 151, Dorsal muscles of the anterior segments of the caterpillar of *Cossus*.

**E. The Motive, or Muscular System.**—The varied structures which we have observed in the preceding parts of this article, upon the external anatomy of insects, are but the visible expression of certain principles which constitute the economy of the various species, and which are regulated in the performance of their various functions by a series of internal muscles, attached to the internal surface of the external covering of the animal. Of the extent of this

system of muscles, some idea may be entertained, when it is stated that Lyonnet discovered 4061 in the caterpillar of the goat moth, 228 being attached to the head, 1647 to the body, and 2186 to the intestines; whereas, in the human body, only 529 have been discovered; so that this insect possesses nearly eight times as many muscles as there are contained in the human frame. This, however, will not appear so extraordinary, when the greater number of legs, &c., in the insect are remembered.

The construction of insect muscles is similar to those of the higher animals, each being formed of muscle and of tendon; the former is fleshy, whilst the latter, which forms the coating and extremities of the muscle, is firm, and not liable to contraction. According to Lyonnet, the muscles are composed of many parallel bands, consisting of bundles of fibres enveloped in separate membranes; these fibres appearing to be twisted in a spiral direction. These muscles are attached at one end to the various processes of internal surface of the outer covering, which serves as their fulcrum, and the other end is attached to the organ to be moved. The size of muscles is proportioned to the movements to be performed by the organs to which they are attached: thus, the muscles of the mandibles are much more robust than those of the maxillæ: in like manner the comparative size of the various organs influence that of the corresponding muscles. Thus, when the anterior wing is enlarged at the expense of the posterior, the mesothoracic muscles are more developed than those of the metathorax; and *vice versa*, in like manner, the muscles of the hind legs of a leaping insect, as a grasshopper, are more extensive than those of the simple walking legs. Muscles, as regards their action, are either flexors or extensors, levators or depressors: by the flexors, which are attached to the inner surface of a limb, it is drawn towards the base, and consequently as it were folded up; extensors, on the contrary, are attached on the exterior part of the cavity of the outer covering of a limb, and acting in an opposite direction, so as to extend the limb. In like manner levator muscles cause the elevation of a limb, whilst depressors bend it downwards. To describe in a more particular manner the muscles of insects, or to trace their varied action in effecting the varied motions which are exhibited by these animals, would occupy a far greater space than we can by possibility devote to the subject in this already too long article.

4thly. *The Physiological and Instinctive Properties of Insects.*

Having got to a close our review of the general structure of insects, as exhibited not only in their preparatory and perfect states, but also in their external and internal organisation, it would naturally remain for us to lay before the reader the modes of operation by which each of these various structures is rendered serviceable towards the fulfilment of the ends for which the insect has been produced. This would comprise every physiological peculiarity presented to us by the insect world, independent of mere structural modification. But in treating of the internal systems of organs, and, indeed, partially, in our review of the external form of insects, we have thought it might be more agreeable to the majority of our readers to blend together effects with causes; operations with the apparatus whereby they are effected. It still, however, remains for us, as previously observed, to notice the operations of that

power, or principle, which seems totally independent of organisation, and to which the name of instinct is generally applied.

It is necessary for us, however, in the first place, to premise, that it is not our intention to enter into any disquisition upon the nature of instinct. We know, indeed, nothing of the real nature thereof beyond what is exhibited to us by the various phenomena of insect life, and which have been well described as the result of a power "enabling an animal to do that which, in those things that man can do, results from a chain of reasoning; and in things which men cannot do, is not to be explained by any efforts of the intellectual faculties \*."

Now these varied phenomena are manifested to us in an endless variety of methods: in the affection of insects for their offspring; in the numerous distinct modes in which the parent insect deposits her eggs in the most appropriate situations; in the construction of nests; in the various stratagems by which insects procure their food; in the modes of defence employed by insects either against their ordinary enemies or accidents; but, more than all, in the varied economy of social insects—bees, humble bees, wasps, ants, white ants. All these varied phenomena appear, however, to be resolvable to two principal heads—the continuance of the species, and the preservation of the individual: indeed, the great end and final care of the endless labours of the social insects can only be traced to one or the other of these causes.

If we confine our attention to the first of these grounds of inquiry, viz. the perpetuation of the species, we find that here, as elsewhere, the great command "Increase and multiply" is obeyed to the fullest extent, as is manifested by the various circumstances connected with the pairing of insects, and especially by the precautions which the parent female exhibits in the careful deposition of her eggs, as already noticed in the early part of this article; whilst the often extraordinary and always interesting peculiarities exhibited by social insects in the construction of their nests, for their own habitations and the rearing of their offspring, the collecting of food, and the feeding of young, have been treated upon in various other articles of this work (ANT, BEE, FORMICIDÆ, HUMBLE BEE, ICHEUMONIDÆ, &c.).

If, on the other hand, we direct our attention to the preservation of the individual (and many of the peculiarities of social insect life conduct us to this branch of our inquiry), we find the subject also divides itself into two sections, namely, the various stratagems employed for obtaining a supply of food, and the means of active or passive defence adopted by insects. With a few notices of some of the most remarkable of each of these instinctive peculiarities, we shall close the present branch of our subject.

We have seen in the early part of this article that, from the very nature of the functions of the insect tribes, it is essential that the consumption by them of animal and vegetable matter should uninterruptedly be carried on. Hence, as well as from the nature of insects in general, and the great care shown by the female in depositing her eggs in the most fitting situations, there is but little occasion for any exhibition of instinctive reasoning on the part of these animals, with the exception of those which prey upon living

\* Lieut. Col. Sykes, in Trans. of Entomol. Society, p. 106.

animal matter. Here pursuit, search, or some equivalent thereto, is necessary for ensuring a due supply of food, and hence we find that the predaceous tribes of insects, like their analogues among beasts or birds, are more fitly organised for rapid movements than the lazy inactive herbivorous species. If this be the case with the perfect insects, there must be some other mode of obtaining their food by their predaceous larvæ (especially since it is during this period that feeding is the great object of an insect's existence), which are not furnished with sufficiently powerful organs of locomotion. We have described the extraordinary mask of the larva of the dragon-flies, which consequently is an instrument applicable for such purpose; and the raptorial structure of the fore-legs of many predaceous insects, the great strength of muscles by which these organs are moved, and the many strong spines with which they are armed, are in like manner auxiliaries, supplying the want of powerful locomotive organs. But there is still another class of predaceous larvæ which are compelled, in order to obtain their own food, to resort to actual stratagems for this purpose, which the more developed structure of the preceding insects rendered unnecessary. The constructions of the spider, and especially the manœuvres of the jumping spiders, so constantly to be noticed on every sunny wall, leaping from a considerable distance upon their prey, will also occur to our readers, but which we shall more especially notice elsewhere.

The larva of a somewhat rare British species of the Linnæan genus *Cimex* (*Reduvius personatus*), is asserted to feed upon the bed-bug; like it, it is found in houses, but its appearance is so extraordinary, that it is impossible to have the least idea that it is an insect, were it not for its slight and awkward movements. It covers itself completely with a coat of dirt and dust, so that it more resembles a lump of earth. Nevertheless the antennæ and rostrum are similar to those of the perfect insect, and enable us to decide what it really is; moreover, on touching it with the point of a pencil, its coat falls off at once, which, however, the insect soon again renews. In this dress it is enabled to approach its prey without their being alarmed at its coming.

There are, however, three species of insects belonging to as many distinct orders, *Coleoptera*, *Diptera*, and *Neuroptera*, which in their larva state exhibit a greater degree of instinct than any of the preceding, by the construction of pitfalls, in which they lay in wait for every stray insect which may be hapless enough to come within their reach. We have already described the burrow of the larva of the *Cicindela*, consisting of a long and tubular passage, at the mouth of which the voracious larva stations itself, its head just fitting the opening of this retreat with its jaws expanded, ready to seize on every passing insect. The two other species referred to are the ant-lion (*Myrmoleon*) and a fly (*Rhagio vermileo*). These construct large funnel-shaped burrows in sandy situations, at the bottom of which they take their station, ready to seize any ant or other insect which may chance to slip down the sides. The grub of the latter lies motionless at the foot of the burrow, and, snake-like, twines itself round its prey, piercing it with its strong hooks or mandibles. But the ant-lion is more wary, its form is most unprepossessing; it therefore buries itself in the sand at the bottom of its hole, leaving only its long curved jaws exposed; and it has the additional instinct, in case any of the insects which

fall down the sides of its trap should endeavour to escape, to bring them within its reach by a shower of sand. We must, however, reserve our details of their proceedings for the article *MYRMELEON*.

The various modes of active or passive defence adopted by insects, present us equally with many of the most interesting phenomena of insect instinct. Here we find Nature ever rich in resources, the smallest as well as the largest objects of the animated creation are equally beneath her care. We will run through the various orders of insects, and notice a few of the more remarkable of these peculiarities. We find the predaceous beetles well enabled to defend themselves, not only by the hard scaly covering of their bodies, and the powerful organs of their mouths, especially their strong and hooked jaws, but also by the emission of a black and fetid fluid, which is quite sufficient to ensure them from the attacks of their enemies. It is this fluid, which is occasionally volatilized on coming into contact with the air, that the bombardier beetle employs when in danger, as described in our article upon that insect. The predaceous water-beetles also, by similar emissions, but more particularly by their capability of flight in the air, swimming in the water, or creeping on the land, are enabled to avoid the attacks of enemies which might assault them in any of these elements. We have seen that many beetles, as the pill-beetles (*Byrrhidae*), the death-watches (*Anobium*), and the mimic-beetles (*Histeridae*), with many others, possess in a remarkable degree the power of counterfeiting death, by folding up their limbs and keeping them in a state of inactivity. Other beetles, by the similarity of their appearance to the sand or earth in which they reside, readily elude our observation, as in many sand heteromera. The emission of similar fetid scents and fluids by many other beetles, as the *Silphidae*, *Chrysomelidae*, and especially by the lady-birds, is a very ordinary means of defence; whilst the similarity in the colouring of others to the leaves, stems, or bark of plants and trees, is equally serviceable. The threatening aspect of some, as the devil's coach horse; the rapidity of the movements of others, as the *Halictæ*, joined to their minuteness, all tend to the same end. The larvæ of the *Cassidæ* and *Crioceridæ* cover themselves with a cloak formed of their own excrements, as described in our articles upon those insects.

In the *Orthoptera* we find great locomotive powers, as exhibited by the locusts and grasshoppers, whose strength in leaping is known to every schoolboy; but there are other insects belonging to the same order equally well defended, although their locomotive powers are but slight. Here we are to notice the walking leaf-insects and the walking stick-insects, objects which to an ordinary observer would appear but detached leaves or twigs rustling with every breath of air; but they have life, and Nature has given them their strange appearance with a view to its preservation, by deceiving those animals which might otherwise make them their prey. Nothing indeed can be more complete than the deception produced by these insects: the walking leaf is flat, semi-transparent, narrowed at the head, or stalk part of the leaf, the antennæ forming the stem, the abdomen is dilated at the sides, notched, like the margin of a leaf, and, to complete the resemblance, the wing-covers lie flat upon the back, forming by their union a straight central line, from which proceeds various oblique nerves, like the principal veins of a leaf. In the neuropterous and tri-

chopterous orders we find equally successful means of defence. We have already quoted a passage relative to the dragon-fly, from which it will be seen how completely, by means of wings, eyes, and mouth, it is enabled to escape its enemies. The delicate gauze-winged golden-eyed flies (*Hemerobius*), which seem too slight to encounter even a breath of air, come forth only at the dusk; they, moreover, emit the most disgusting scent; and, as a still further defence, they have the instinct to place their eggs out of danger, at the extremity of long and slender foot-stalks, and their larvæ cover themselves with a coat formed of the skins of their victims.

The *Phryganeæ* encase themselves, in the larva state, in firm cases of earth, stones, shells, &c., fastened together; and thus their soft and fleshy bodies are secured from the attacks of fishes which, as every angler is aware, deem them a tempting morsel.

Who is there that has not experienced how well some of the insects of the hymenopterous order are enabled to defend themselves by the assistance of their sting? We surely need not describe the pain inflicted by this delicate instrument, which we have described at length in our article BEE.

The *Lepidoptera* are perhaps the most defenceless amongst insects, but even here we find many larvæ having instinct to enroll themselves in the leaves of plants, or to form for themselves tents or tubes of various materials for their abodes; whilst others, by the resemblance of their colours to the plants upon which they are found, or by the hairs with which they are clothed, are amply defended against their foes.

In the hemipterous order we find a very numerous tribe, composing the Linnæan genus *Cimex* (the bugs), able effectually to defend themselves by the emission of a powerful scent, which, although occasionally in some few species not disagreeable, is in general very disgusting.

In the *Hemiptera* many species, as the *Cercopidæ*, are enabled to leap to very great distances, thus avoiding their enemies; whilst some in the larva state conceal themselves beneath a curious coating of froth.

The *Diptera* do not present any very striking instances of insect defence; the rapidity of their motions, as well as those of insects composing the remaining order *Aphaniptera* (the flea), ought not, however, to be omitted.

From this review of the means of defence in the various orders of insects, it will be seen that distinct organs for active defence are not possessed by the majority of these animals, but that they are amply compensated by equally effective modes of counteracting the attacks of their foes, consisting of powers of evasion, as rapidity of flight, strength in swimming, quickness in leaping, and velocity in running; or of repulsive powers, as emission of powerful odours, the hideousness of appearance, or simulating powers, whereby the appearance of death or other objects is assumed.

The various facts which we have now adduced will, we are convinced, be amply sufficient to prove how interesting is the study of this class of animals. Here all is motion, all manifests in the strongest degree the desire to prolong existence, and to perpetuate the countless insect tribes. The constant dread of destruction to which, from their small size, insects are so pre-eminently liable, and against which their instinct, in all states of their existence, is

brought into full action, is nevertheless necessary to preserve a just proportion between all the tribes of the creation. Here indeed we may safely believe—

All discord, harmony, not understood,  
All partial evil, universal good.

Under whatever aspect we consider the little objects of our present consideration, if we admire the variety of their forms, the beauty of their colours, the diversity in their habits, the surprising development of their instinctive faculties, or the great part which they take in keeping up the harmonies of nature, we no longer marvel that so much care has been bestowed in their construction, or that so many good and learned men have endeavoured to study them in their various relations. Here we have seen structure and function admirably adapted to each other; here, in these tiny wheels of the great machine of the creation, we see developed and put in motion, even by a single glance of the unassisted eye, but still more admirably by the assistance of the microscope, the great resources of the Great and Almighty Machinist of all things. It is surely here, amongst the most perfectly organised tribes of the lower animals, as well as in the most stupendous objects of the animated world, that we trace “the Wisdom of God in the works of the Creation.”

“Full nature swarms with life; one wondrous mass

Of animals or atoms organised,  
Waiting the vital breath when Parent Heaven  
Shall bid his spirit blow. The hoary fen,  
In putrid streams, emits the living cloud  
Of pestilence. Through subterranean cells,  
Where searching sun-beams scarce can find a way,  
Earth animated heaves. The flowery leaf  
Wants not its soft inhabitants. Secure,  
Within its winding citadel, the stone  
Holds multitudes. But chief the forest boughs  
That dance unnumbered to the playful breeze,  
The downy orchard and the melting pulp  
Of mellow fruit, the nameless nations feed  
Of evanescent insects. Where the pool  
Stands mantled o’er with green, invisible  
Amid the floating verdure, millions stray;  
Each liquid too, whether it pierces, soothes,  
Inflames, refreshes, or exalts the taste,  
With various forms abounds. Nor is the stream  
Of purest crystal, nor the lucid air,  
Though one transparent vacancy it seems,  
Void of their unseen people.

Let no presuming impious railer tax  
Creative Wisdom as if aught was formed  
In vain, or not for admirable ends.  
Shall little haughty Ignorance pronounce  
His works unwise, of which the smallest part  
Exceeds the narrow vision of her mind?  
As if upon a full-proportioned dome  
On swelling columns heaved, the pride of art,  
A critic fly whose feeble ray scarce spreads  
An inch around, with blind presumption bold,  
Should dare to tax the structure of the whole.  
And lives the man whose universal eye  
Has swept at once the unbounded scheme of things,  
Mark’d their dependence so, and firm accord,  
As with unflinching accent to conclude  
That this availeth nought? Has any seen  
The mighty chain of beings lessening down  
From infinite perfection to the brink  
Of dreary nothing, desolate abyss!  
From which astonished thought, recoiling turns?  
Till then, alone let zealous praise ascend,  
And hymns of holy wonder to that Power  
Whose wisdom shines as lovely on our minds,  
As on our smiling eyes his servant sun.”

Section 5. *Classification of Insects.*—We have now arrived at another branch of our subject, which, in many respects, is especially deserving the notice of the student, namely—the classification of insects, which has engaged the attention of naturalists in all ages. This portion of entomological science divides itself primarily into two points of view: firstly, an inquiry into the nature of the various relations exist-

ing amongst insects; and, secondly, the mode of application of these relationships, either with a view to the construction of an arrangement most fitly adapted for the artificial bringing together of objects, so as to enable the memory with least difficulty to retain an idea of their various characters, distinctions, and names, or, with a higher view, of endeavouring to trace out, by the strict application of their relationships, the general plan by which the wondrous whole has been so beautifully arranged.

We have heard it maintained, by men whose views of natural history have been based upon a too partial examination of a few isolated species of some limited groups of animals, that, except in the relations existing between the sexes of a species, or the sexes of distinct species which might accidentally couple together, or between a predaceous insect and the insects upon which it preys, there can be no such thing as a relationship amongst insects. And this view of the subject is endeavoured to be supported by the argument, that the various species of the group which we term a family or genus, are totally independent of each other in all their relations of life, and that the annihilation of one species would in nowise influence the remaining species.

Now, all this may be, and much is certainly true; but we submit, that this is a most partial mode of looking at the relations of animals, even in a natural history and economical point of view. We ordinarily employ the term relationship to designate that bond of community existing amongst the members of a family; but there are numerous other species of alliances to which we may also give the general term of relations. And it is upon these undeniable relations, affinities, analogies, resemblances—call them as you will—that the classification of all animals are founded. And the more perfect our knowledge of any animal, in all its states, and in all its relations to all other animals, the more correctly are we enabled to give due weight to every peculiarity, whether structural or functional, which it exhibits; and thus to trace its more or less contiguous relations with other animals. Again, if we look at the habits of insects, we find some exhibiting a similar predaceous economy; others are vegetable feeders; some attack particular species of animals; others particular species of plants. Now each of these groups of species will, both from economy and from structure dependent upon economy, exhibit more close relations amongst their respective members than the species belonging to groups possessing opposite habits. Hence we may be induced to affirm, as has been done by a celebrated writer, Dr. Fleming, that we shall have as many systems of animals as there are variations of function. And thus, animals differing from each other, except in one isolated particular, are thought to be more nearly related together than they are to other species, to which, in all their other particulars, they are more intimately allied. But this also appears to us to be an equally incorrect and partial view of looking at nature. We have given too great a weight to such an isolated peculiarity: we will endeavour to illustrate this view of the subject by a reference to the recently published volume of the Count de Saint Fargeau, upon hymenopterous insects, in which we find the social character of these insects regarded as outweighing all other characters. The result of this is, that we have the ants, wasps, hive bees, and humble bees, united together, whilst the solitary wasps, and

the *Psithyri* (as noticed in the article HUMBLE BEE), and all other solitary or parasitic bees, are separated; although their structure is in every respect almost identical, except in the organs, which are necessarily modified in the former, so as to be fitted for the duties of their social character. Now this mode of distribution appears to us to be erroneous, because too limited in respect to the great workings of the creature. These social habits, as we have seen, are but the results of a modification of the instinct for securing the development of the progeny of these particular species, whilst the great object of these insects in nature is overlooked. The solitary bee which burrows in rotten wood, and then forms its cell, exhibits as much instinct as the humble bee which is the foundress of a community. The wonders of the hive are but the exhibition of a more highly developed instinct in building and provisioning a nest. "In rejecting from the family of the humble bees," observes Saint Fargeau, "the *Euglossæ* of Latreille (which that author had always inserted in the same group with the former), I may remark, that in a system (*dans un système*) the very long tongue may indicate a relationship between *Bombus* and *Euglossa*. But in a natural method (*une méthode naturelle*), this length only indicates that both are destined to gather honey from flowers having long and narrow tubes, although their habits are in other respects entirely different, as indicated by the structure of their hind legs\*." Here, however, the difference in habit between these two tribes of bees are only such as are immediately connected with their social or solitary nature, their entire structure being in other respects similar; thus indicating that, except in this single circumstance, the entire system of the two groups must be as nearly as possible identical. Thus too much weight appears to have been given to the social conditions of the *Bombi*, and the characters of structure resulting therefrom. And, in like manner, the same remark may be applied to all classifications founded on the presumed superiority of an isolated character, independent of the question of its real value, as proved by the functions for which it is bestowed. And herein lies one of the great obstacles in the way of our tracing the real relationships of animals. Thus one author will maintain that the metamorphoses of insects are entitled to the first consideration; and will hence insist that the all-devouring locust and the suctorial bug are closely allied together. Another will give the same weight to the organs of the mouth, and, denying the relationship between these two insects, will assert that the one is more nearly allied to the mandibulated *Neuroptera*, and the other to the suctorial *Lepidoptera*; whilst a third will maintain the superiority of the wings, and thus bring the mandibulated *Hymenoptera* and the suctorial *Diptera* into contact. Now all these variations of classification do not prove that there are no such things as relationships existing amongst these tribes of insects; but simply that the correct mode of applying the various characters, so as to correspond with their natural relationships, has not been discovered.

These relations, whether of structure or of habit, must have presented themselves to every one who has paid the least attention to natural objects. Let us take an example or two. We have already asked

\* "Hist. Nat. des Insectes Hyménoptères."—Paris, 1836, p. 438.

our readers (in treating of the defences of insects), whether we need enter into detail, relative to the stings of hymenopterous insects, the pain arising from which must probably, at one time or other, have been experienced by all? Now every one knows that wasps, as well as hive bees, are stinging insects. This circumstance, then, insures the existence of one species of relationship (that resulting from functions); but if we take the trouble to notice these two insects more particularly, we shall find they possess numerous other characters in common. Both are provided with membranous wings of unequal size; both are social in their habits; both are similarly organised in the structure of their antennæ, and in the number of their abdominal rings. Here, then, we find so many points of resemblance, that we at once admit the existence of a relationship, or similarity so close, that it cannot have escaped the most indifferent observer. This intimate kind of relationship is termed an affinity. But there is another kind of relationship which must have been equally observed by every observer of nature. We have already taken the wasp and the bee as our guides, and here again they will serve our purpose. Whoever has walked, during the heat of the day, in any woody situation, must have observed various bee and wasp-looking insects hovering about in the sunbeams, and darting away on being approached with an astonishing rapidity. These are not, however, bees nor wasps, neither do they belong to the same order as these insects, although they are sometimes called drones, when seen settling upon flowers; which name is also given to the male honey bee. We have given figures of these insects, in order to exhibit their resemblance, in the article ENTOMOLOGY (page 430). Here there is no real affinity, no resemblance extending through a series of particulars. Habits, structure, wings, legs, antennæ, are all different, when examined with precision; and yet, on a casual glance, the general appearance of the two insects is so similar. This distant kind of relationship is termed an analogy. Further; as there are instances in which a similarity of appearance may thus exist without any real affinity, as regards the structure of essential organisation, so, on the other hand, are there numerous instances in which a direct affinity, resulting from similarity of the essential organs, exists between two insects, although their general appearance be quite unlike each other. Of this masked kind of affinity, numberless instances might be produced. Thus an heteromorous insect, related by affinity to *Tenebrio* and *Helops*, so closely resembles some of the predaceous beetles, that Fabricius called it a *Carabus*; and Mr. Kirby has described several allied species under the names of *Adelium*, *Caraboides*, *Calosomoides*, and *Licinoides*. We have further to notice, that as there are more than one species of hive bees dispersed over the globe, so there are other social species of wild honey bees: in like manner there are as many species of wasps and hornets. Each of these groups of species constitute a certain series; and thus we discover some of the links of a chain extending throughout nature. Now it is impossible to adopt these views without, at the same time, admitting that all these beautiful and harmonious affinities and analogies could be bestowed upon animals without any regard to some fixed system.

"Order is heaven's first law,"

and the naturalist must be blind, indeed, who cannot

trace in the beautiful gradations of form, and the various relationships of animals, the marks, slight enough in too many cases, of a universal system, wherein just regard is paid to every peculiarity, and every structure shown in juxtaposition with allied structures, none being excluded. This is termed the *natural system*; but in what manner the knowledge, of this system is to be attained, whether, as appears generally to be supposed by a review of mere structural peculiarities, or by selecting the general functions of each species or by taking into consideration its geographical range—whether the system be a linear series or a circular one—whether it be supposed to resemble the intricacies of a map\* or a sphere; whether it be resolvable throughout its divisions in a binary (Dr. Fleming and Haworth), trinary (Swainson), quaternary (Fries), quinary (Mac Leay), or septenary manner (Newman); whether we confine ourselves to the now existent species, or have regard to the countless multitudes of extinct species; whether by means of any of these proposed modes or any other, it must be evident that natural history, and especially philosophical natural history, is too new a subject to allow any one to assert that his system, and his only, is superior to all the rest. Great progress has been made of late years in this field; but how great is the yet untrodden portion we have to labour at unceasingly; and he who, by a minute analysis of any animal, enables us to solve any dubious point connected therewith, does more for the elucidation of this much abused natural system than the greatest and most ingenious theorist who has yet taken the subject in hand.

The celebrated Cuvier, whose laborious researches and acute reasoning made such vast strides in the philosophy of natural history, and effected as great a revolution in received opinions as was ever brought about by one man in any science, was fully sensible of the correctness of these opinions. He laboured not to support system, but to discover the truth; and the further he advanced, seemed the more convinced that he did not know enough to enable him to form a system. And if this were the case with the greatest comparative anatomist who ever lived, how truly must the same remark be made of those who, without having ever touched the dissecting knife, sit down to construct, out of the workings of their own fanciful and ingenious brains, the natural system. Speaking of such theories, Cuvier, a little before his death, said, "I have sought, I have set up some myself, but I have not made them known, because I have ascertained that they were false, as are all those which have been published up to this day. I affirm still more; for I say that in the present state of science it is not possible to discover one, and it is for this reason that I persevere in my observations, and that I continue to publish them. This perseverance only can lead to the truth. We ought to labour, not with the object of supporting a theory, because then the mind, being preoccupied, will perceive only that which favours its own views; our labours should be for the object of discovering the truth."—Memoirs of Cuvier. The writer of the present article, who had the honour of a personal acquaintance with this celebrated man, can testify how completely these were his real sentiments.

\* Linnaeus, in his *Philosophia Botanica*, thus speaks of the natural system as exhibited by plants, "*Plantæ omnes utriusque affinitatem monstrant uti territorium in mappa geographica.*"

Taking into consideration the immense number of species of insects, which, as we have already observed, so far exceed all the other animal subkingdoms; it must, however, be evident, as Mr. Mac Leay observes, that it is here, owing to their myriads of species, that the mode in which Nature's chain is linked—a mode, the knowledge of which comprises all knowledge in natural history—will be most evident, and therefore most easily detected. This same circumstance also is attended with another consequence. If the species of insects (and, indeed, of any tribe of animals) be so numerous, and their natural distribution so difficult of attainment; and yet, nevertheless, if we would retain and extend the knowledge which we already possess, either of their structure or habits, it must be evident that this can only be done by distributing their groups in the most convenient mode for reference. This may, and, indeed, must be done in an *artificial method*; that is, we select certain constant characters which may, nevertheless, possess but very little influence upon the habits of the animal, and which, indeed, in many cases, compel us to separate groups which we know to be naturally allied by affinity with each other. Thus we separate the wasps from the bees, because the former fold their upper wings longitudinally when not flying; and thus we divide the beetles according to the joints of the tarsi, although in some instances direct affinities are thereby separated.

Nevertheless, the great advantages resulting from an artificial method are so obvious, that we find them admitted by persons who do not hesitate to reject, as an absurd fancy, the existence of a natural system. These advantages will appear the more evident when we investigate the actual number of insect species. Our great and pious naturalist, John Ray ("le premier véritable naturaliste pour le règne animal," as the equally great Cuvier has styled him), in his "Wisdom of God," published at the close of the seventeenth century, tells us respecting the number of British insects: "The butterflies and beetles are such numerous tribes, that I believe in our own native country alone, the species of each kind may amount to 150 or more. The fly kind (if under that name, we comprehend all the flying insects, as well such as have four, as such as have but two wings, of both which kinds there are many subordinate genera), will be found in multitudes of species to equal, if not exceed, both the forementioned kinds. The creeping insects that never come to be winged, though for numbers they may fall short of the flying or winged, yet they are also very numerous. Supposing then there be a thousand several sorts of insects in this island and the sea near it; if the same proportion holds between the insects natives of England and those of the rest of the world, as doth between plants domestic and exotic (that is, as I guess near decuple), the species of insects on the whole earth (land and water) will amount to 10,000, and I do believe they rather exceed than fall short of this sum." Subsequently, however, in consequence of having discovered a greater number of English moths and butterflies, he was induced to consider that the total number of British insects might be about 2000, and those of the whole earth 20,000. Mr. Stephens, however, in the most perfect catalogue of insects ever yet published, devoted to the British species, has introduced not fewer than 10,000 native species, and perhaps 2000 or 3000 remain unnoticed.

Linnaeus, in the edition of 1761, of the Fauna of Sweden, described 1700 species; and in the twelfth edition of the Systema Naturæ, the entire number of these animals (Swedish and exotic), with which he had become acquainted, amounted to about 3000; but during the last half century the investigation of insects has so much progressed, that Mr. Mac Leay, in his *Horæ Entomologicae*, published in 1821, stated that there were certainly more than 100,000 of the annulose animals (nearly synonymous with the Linnaean insects), preserved in the various collections. The latest insect census is, however, that of Dr. Burmeister, who states that there are in Germany about 6000 plants (including *Cryptogamia*), and more than 12,000 insects; so that, if this proportion be constant, the number of known insects, according to the 60—70,000 known plants, will amount to 120—140,000 species; and if the opinion of the latest botanists be adopted, that about one-third of the collective species of plants are known, the number of species inhabiting the earth would amount to 360—420,000 species. Kirby and Spence, indeed, averaged six species of insects to one phanerogamous plant, and considering there may be 100,000 species of phanerogamous plants in the world, they obtain the number of 600,000, or more probably 400,000 species of insects. There are computed to be 28,000 species of beetles in the royal collection at Berlin; and from the supposed superiority of the extent of the coleopterous order, Dr. Burmeister considers that the actually known species of insects may be thus distributed:—

Coleoptera . . . . .	36,000
Lepidoptera . . . . .	12,000
Hymenoptera . . . . .	12,000
Diptera . . . . .	10,000
Hemiptera . . . . .	4,000
Other insects . . . . .	4,000

Mr. Stephens's British catalogue shows the following proportions; but it must be observed, that the attention lately bestowed upon the minute *Hymenoptera* and *Diptera*, have raised their numbers very considerably:—

Coleoptera . . . . .	3300
Lepidoptera . . . . .	1838
Hymenoptera . . . . .	2054
Diptera . . . . .	1671
Hemiptera . . . . .	605
Other insects . . . . .	544

Now it must be evident, that unless some convenient and easily applicable mode of classifying these vast masses be adopted, the mind will be compelled to remain in a state of the most profound darkness. We will not, however, dwell upon this subject, but refer our readers to the article CLASSIFICATION.

The annulose, or insect sub-kingdom, is divisible into the four classes above mentioned; viz., *Crustacea*, *Arachnida*, *Ametabola*, and *Pilota*, or winged insects; which last Mr. Mac Leay separates into two distinct classes, as mentioned in our observations on the mouth of insects; namely, *Mandibulata* and *Haustellata*. These classes are again divisible into orders.

Linnaeus adopted the structure of the wings as affording the characters of his orders, which were as follows:—

1. *Coleoptera*.—Wings four, the upper pair crustaceous with a straight suture (beetles and earwigs).

2. *Hemiptera*.—Wings four, the upper pair semi-crustaceous and incumbent (bugs, locusts, tree-hoppers, plant-lice, &c.).
3. *Lepidoptera*.—Wings four, imbricated with scales (butterflies, moths).
4. *Neuroptera*.—Wings four, membranaceous, anus unarmed (dragon-flies, &c.).
5. *Hymenoptera*.—Wings four, membranaceous, anus armed with a sting (bees, wasps, ants, saw-flies, &c.).
6. *Diptera*.—Wings two, halteres two in the place of the posterior wings (flies).
7. *Aptera*.—Wings none (spiders, crabs, centipedes, fleas, &c.).

We have shown above that the possession of wings is the chief characteristic of the *Ptilota*, which may therefore be regarded as the type of the other annulose animals, that is, we may consider them as the furthest removed (as concerns their organisation), from the other animal sub-kingdoms; hence we find, that the orders or first general divisions of insects are characterised from the structure of the wings (*πτερον*, a wing); and hence this Greek word, together with some other prefixed to it, is employed as the name of orders. We have thus *Coleoptera*, sheath-winged, *Neuroptera*, nerve-winged, &c.; but it soon became evident, that the characters of the wings were too general; and Fabricius, a disciple of Linnæus, fell into the opposite error of regarding the variations of the mouth as alone affording the most satisfactory distribution of insects.

The system of Fabricius introduced a number of new orders, which he was pleased to name classes; and to which, in addition to such of the Linnæan orders as he retained, he gave a series of exceedingly harsh names, founded upon the structure of the mouth, as follows:—

*Insects with masticating mouths.*

Two pairs of jaws.

*Eleutherata*. Maxillæ palpigerous, uncovered (beetles).

*Ulonata*. Maxillæ palpigerous, covered with a galea (locusts, mantes, &c.).

*Synistata*. Maxillæ palpigerous, connate with the lower lip (lace-winged flies, &c., with the white ants and sugar lice).

*Piezata*. Maxillæ palpigerous, distended, thin, coriaceous (bees, wasps, saw-flies, &c.).

*Odonata*. Maxillæ palpigerous, horny, toothed, labium not palpigerous (dragon-flies).

*Mitosata*. Jaws and maxillæ not palpigerous (centipedes, &c.).

A pair of jaws resembling scissors.

*Unogata* (scorpions and spiders).

More than two pairs of jaws.

*Polygonata*. Jaws closed by the lower lip (sea and wood lice, *Oniscus*).

*Kleistagnata*. Jaws external, closing the mouth beneath (crabs).

*Exochmata*. Jaws external, but covered by the palpi (lobsters, &c.).

*Insects with suctorial mouths.*

*Glossata*. Mouth with a spiral tongue (butterflies, moths).

*Rhynchota*. Mouth with a membranous jointed sheath, inclosing horny lancets (bugs, tree-hoppers, &c.).

*Anthiata*. Mouth with a soft unjointed proboscis (flies, lice, and mites).

As the Linnæan system, founded upon the wings, was found to violate nature by uniting masticating and suctorial insects, so the Fabrician system was, in some respects, even more artificial, as when the wingless sugar-lice, which undergo no metamorphoses, were introduced amongst the metamorphic lace-winged flies, &c., and the lice and octapod mites (*Acari*) were united with the two-winged flies. The system of Fabricius has met with but few followers, except in Germany, his chief merit consisting in his definition of a great multitude of new species. To the labours of the French naturalists, Cuvier, Latreille, and Lamarck, we are mainly indebted for the great advances made towards a more natural mode of distribution, wherein the natural affinities of the various groups are more or less recognised. It would occupy too much time to trace the gradual improvements, or suggestions for improvements, which have been made during the present century, in which Entomology has made such rapid strides towards perfection. We shall, therefore, content ourselves with translating for the student the characters of the various orders of metamorphic insects, given in the last work of Latreille, the *Cours d'Entomologie*, published shortly before his death, and which are generally adopted. Latreille, however, has introduced the spring-tailed insects (*Thysanoura*), and lice (*Anoplura*), at the head of the class of insects which, as above stated, we have, with MacLeay, united with the *Ametabola*, as they undergo no metamorphoses.

- I. Wings none, metamorphoses complete (perfect), larva apod, pupa inactive, mouth formed of an inferior syphon, directed backwards, composed of a bi-valved articulated sheath, inclosing a sucker of three setæ, with two scales at the base, body very compressed, formed for leaping. Insects parasitic (fleas).

Order, *Siphonaptera*.—Mr. Kirby's name, *Aphaniptera*, ought to be retained in preference either to Latreille's name, or that of *Suctoria*, given to the flea by De Geer.

- II. Wings, sometimes, however, obsolete; eyes faceted, and occasionally ocelli.

1. *Elytroptera*.—Posterior wings, covered by the anterior, which are either entirely or partly crustaceous or coriaceous.

- A. Mouth with upper jaws, and lower jaws; elytra of an uniform consistence.

Order, *Coleoptera*, characterised by, Elytra entirely crustaceous, always horizontal, with a straight suture; wings folded cross-wise; external lobe of the maxillæ not helmet-shaped; metamorphoses complete (pupa incomplete), beetles.

Order, *Dermaptera*.

Elytra entirely crustaceous, horizontal with a straight suture; wings folded transversely and partly longitudinally, so as somewhat to resemble a fan; maxillæ with the terminal lobe helmet-shaped; two strong pincers at the posterior extremity of the abdomen in both sexes; demi-metamorphoses (pupa complete and active), ear-wigs.

Order, *Orthoptera*.

Elytra (tegmina) coriaceous, deflexed or inclined, in some horizontal, and folding on each other at the internal edges in the others; wings longitudinally folded throughout their entire length; maxillæ, with the terminal external lobe, helmet-shaped; abdomen terminated by articulated appendages in both sexes in some; in the others, the abdomen furnished with

an external ovipositor; demi-metamorphoses (pupa complete and active, locusts, grasshoppers, mantes, cockroaches).

B. Mandibles and maxillæ none; a rostrum, or sort of proboscis, formed of an articulated sheath, inclosing a sucker of four pieces; elytra (hemelytra) membranous at the extremity in some species; demi-metamorphoses, except in a few (pupa complete and active),

Order, *Hemiptera*.

2. *Gymnoptera* (naked wings).

No elytra, four or two naked wings.

A. Four wings.

a. Upper and lower jaws; wings generally transparent, not farinose; tegulæ, (scales placed at the base of the upper wings) small and tubercular.

Order, *Neuroptera*, with the

Wings thickly reticulated; the posterior of the same size as the anterior, or longer or larger: no exerted ovipositor in the majority; no sting, metamorphoses various.

Order, *Hymenoptera*, with the

Wings horizontal, with large areas, or simply veined, the posterior smaller than the anterior; maxillæ often valvular, laterally sheathing the tubular lower lip, and forming a species of rostrum (promuscis) more or less elongated; an exerted ovipositor, or an anal sting in the majority of the females.

b. Mandibles rudimental; maxillæ replaced by a spiral rostrum (spirittrompe), formed of two fillets, tubular, and rolled up in a spire, united between two labial palpi; wings farinose, tegulæ (pterygodes), large, epaulette-shaped, turned backwards,

Order, *Lepidoptera* (butterflies, moths).

B. Two wings.

Order, *Rhipiptera* (Mr. Kirby's name, *Strepsiptera*, must be retained instead of *Rhipiptera*), with

Two pseudhalteres (prebalanciers), or small crustaceous moveable bodies in the shape of small twisted elytra, placed in front of the wings, which are folded fan-wise; mouth with two setiform pieces, crossed like a pair of mandibles.

Order, *Diptera*, with the

Wings extended, and accompanied in the majority by two small moveable bodies, in the form of balancers, situated behind the wings; rostrum bent at its base, and generally terminated by two fleshy lips. inarticulate, inclosing a sucker formed of a variable number of setæ (flies).

The first of the above described orders, *Aphaniptera*, Kirby, is, in various respects, most nearly allied to the *Diptera*. It will also be observed that the suctorial *Hemiptera* are introduced into the middle of mandibulated insects. These difficulties are necessarily attendant upon our endeavours to arrange our primary groups in a linear series, in which it is impossible to combine all these relations of groups. Thus, if we remove the *Hemiptera* from the situation assigned to it by Latreille, and place it amongst the suctorial insects, we shall violate its relations with the *Orthoptera*, caused by the similarity in its metamorphosis, and in the structure of the wings.

Mr. Kirby has further separated the *Phryganidæ* from the *Neuroptera*, under the name of *Trichoptera*. Mr. Haliday has added another order in the last number of the Entomological Magazine, named *Thysa-*

*noptera*, formed of the genus *Thrips*, Linn. M. Laporte has also proposed several other orders in his *Etudes Entomologiques*.

The reader will find these various orders treated upon at length in their alphabetical situations. It is here only necessary to observe, that each, according to its extent, is divisible into a greater or less number of groups, and gradually decreasing in value, until our arrival at the families (of which we have spoken more at length under our article *CANCERIDÆ*) genera, and species; the last of which, according to the opinions of some authors, is the only absolute division existing in nature.

In every extensive genera it has been found serviceable to introduce minor divisions, which greatly facilitate the acquisition of knowledge. We have, however, already dwelt upon the nature of these minor groups in our article *CANCERIDÆ*, and shall only observe, that in the opinion of some authors (as for instance, Mr. Vigors, in the *Zool. Journal*) their existence ought not to be admitted; or if they present sufficiently distinctive characters, they ought to be regarded as genera, and the next higher group of which they form a part, as sub-families. That the gradual approximation of form in the most extensive groups, where, for instance, it must be admitted that the series, from the number of species, is evidently least unbroken, prevents us from assigning such distinctive limits to our groups, whether of genera (that is speaking theoretically) or sub-genera, as shall comprise those particular species, in which the characters of distinct genera are blended together, cannot be denied. And the great genus of *Carabidæ* (*Feronia*) has frequently been cited. But still even in these kind of groups we find various types of form, which in the typical species of each minor group are so well marked, that if the genus were less numerous in species, entomologists would not hesitate to consider them as so many distinct sub-genera. But by many naturalists the great chain of nature is regarded as formed upon this very mode of confluent characteristics; and were we to admit, in those most extensive and consequently, as we may well suppose, most perfect series of species, the non-existence of genera or sub-genera, we should be compelled to admit still further, that there is no such thing in nature as any other distinct division than that of species; and it would be as correct, in such point of view, to assert that a butterfly is a beetle, as it would be to say that a *Pæcillus* is a *Steropus*. "It appears to be the opinion of most modern physiologists," observe Messrs. Kirby and Spence, "that the series of affinities in nature is a concatenation or continuous series, and that though an hiatus is here and there observable, this has been caused either by the annihilation of some original group or species, in consequence of some great convulsion of nature, or that the objects required to fill it up are still in existence, but have not yet been discovered; and this opinion is founded upon a dictum of Linnaeus's '*Natura salus non facit*.' If this dictum be literally interpreted, according to the evident meaning of the word *salus*, few will be disposed to object to it, since both observation and analogy combine to prove that there must be a regular approximation of things to each other in the works of God; and that, could we see the whole according to his original plan, we should find no violent interval to break up that approximation; but if it be contended that in this plan there is no difference in the juxtaposition of the lowest

groups or individuals, and never any interval between them, I think we are going further than either observation or analogy will warrant. Were this really and strictly the case, it seems to follow that every group or individual species must, on one side, borrow half its characters from the preceding group or species; and on the other, impart half to the succeeding. (Query, whether every real species or group has not some one or more peculiar characters, which it neither derives from its predecessor nor imparts to its successor in a series?). But one of the most evident laws of creation is variety, and if we survey all the works of the Most High, we shall nowhere discover that kind of order and symmetry that this strict interpretation implies. The general march of nature, therefore, seems to say, that there must be varying though not violent intervals in the series of beings, or, in other words, some conterminous species or groups have more characters in common than others."

Very few words will suffice upon the nature of species, a term employed to designate those groups of animals which (save as respects sexual distinctions) possess a perfect conformity in their characters, which indeed they have uninterruptedly possessed since the first establishment of species. The oldest records of natural history, where sufficiently clear to be relied upon, show us that in the species which are therein described or figured, not the least variation has taken place in them. Were not this the case, indeed, there would be grounds for the belief that there are new species of animals produced, which, as Ray says, would certainly now and then, nay very often, happen were there any such thing. But, as in the higher animals, the species of insects are liable to variation, as every collector is well aware; thus, some moths, which have the ground of their wings of a pale colour with dark markings, will be found to have dark wings with light marks. Variations in size are equally common, and entomologists deem it expedient to retain in their collections suites of individuals of each variable species, from the smallest to the largest; sometimes, indeed, the latter are many times larger than the former, a circumstance often occurring in wood-feeding insects. In general also male insects are much smaller than the females. The reader will also bear in mind that this variation in size is not the result of increased growth after arrival at the winged state, and that the small individuals will by and by attain the size of their partners. This is quite contrary to every principle of insect physiology. It is in the larva state that the eating and growing of these animals chiefly takes place. And it would be as requisite for the imago to cast its horny envelope in order to increase its size, as it is for the larva to do the same thing; again, it must be self-evident that without the sloughing, the external envelope could never, from its consistence, undergo the slightest change. Moreover, the change which the digestive organs undergo in the passage from the larva to the imago states, sufficiently proves the same fact. But species often vary even in structure, not indeed in any of the more important organs, but in the various arms with which they are furnished. This is especially the case with the cornuted species, and those which have the mandibles very greatly developed. Here in many instances there appear to be a series of individuals intermediate between the fully developed species and the females, which are generally destitute of these appendages. This we have noticed in many

species of lamellicorn beetles, and in some of the staphylinidæ (*Siagonium quadricorne*). The Rev. Mr. Burrell also observed it in another species of the same group, *Bledius armatus*, of which he describes a variety with horns shorter than the head, although usually longer, and which he is disposed to regard as a neuter, an opinion also entertained by Mr. Haworth, who considers that such neuters are far more frequent, even in the hymenoptera, than hitherto imagined. (Entomological Transactions.) Besides these, which appear to be casual occurrences, there likewise exist what have been termed *permanent varieties* in many species, the individuals of which are found in situations different from the ordinary type of the species, and it has been considered that these variations have originated somewhat in a similar manner to the varieties of domestic animals; but this may certainly be doubted, because in most domesticated insects, the common house-fly, disseminated as it is over the whole surface of the globe, and the hive bee, we find not the least liability to vary; and if this be not the case with these species, we can hardly attribute the production of varieties in species, which are in nowise subject to the rule of man, to a similar cause.

The characters by which species are distinguished are very variable, partaking indeed, in this respect, of the peculiarities which we have noticed in our observations upon generic and sub-generic groups. In very extensive genera the distinctions of species are so minute, that it requires the most practised eye to separate them; and indeed there are some groups, the species of which are so intricately blended together, that no two entomologists are agreed as to their distinctness. The genus *Nothiophilus* (a genus of small *Carabidæ*), affords an instance of this. Until very lately it was supposed to consist of only two British species, Mr. Curtis, however, added another; Mr. Waterhouse, increased the number to eighteen, in a monograph published in the Entomological Magazine; whilst Mr. Stephens has subsequently reduced this number to six. The characters which supply specific distinctions are also very variable, size, sculpture, colour, markings, locality, general forms, are all employed, and it often happens that a character, which in one group of insects would be deemed of sufficient value to characterise a genus, is in others only serviceable as a specific mark of distinction; thus in the genus *Rhipiceræ* (a group of exotic beetles, with beautiful pectinated antennæ); these organs vary in the number of their joints; whereas we have seen, that in a whole section of hymenoptera (*Aculeata*) the same number of joints runs throughout the whole.

In describing species of insects it is usual to give a short character embracing the most striking characteristics of the species. This is ordinarily in Latin, that language being universally regarded as peculiarly adapted to science, being universally understood wherever science exists; indeed the neglect of this plan, which we often notice in French and German, and sometimes in English authors, shows a disregard to a settled and most convenient custom, enabling persons unacquainted with those particular languages to identify, in some degree, a species, although the more extended description may be written in either of these or any other tongue. It is usual also to add the length of the body and expansion of the wings, these admeasurements being taken in inches and lines, which are the tenth parts of an inch.

To each species of insect two names are given, namely, a generic, and a specific one; as, for instance, *Acherontia atropos*, or the death's-head moth, an insect which we now mention in order to refer to our article thereon for some observations upon the advantages resulting from the employment of specific names over the old verbose mode of distinguishing species. The names of species are ordinarily derived from, or are, Latin words, expressive of some specific peculiarity. Thus we have *Phalœna mori*, the silk-worm moth, or moth of the mulberry-tree; *Melolontha solstitialis*, the summer cockchaffer; *Mutilla Europœa*, the European mutilla; *Carabus violaceus*, the violet-coloured carabus, &c. &c. From the great advantages resulting from the specific names, it is highly essential that they should be unchangeable. The Linnæan names have consequently and constantly a pre-eminence, the great Swede having first introduced them into natural history. In like manner, the name imposed upon any new species by the original describer thereof, is retained in preference to all subsequent ones; unless, indeed, some signal error should have occurred in the imposition of the original name. Here, however, it is necessary that we do not permit our love of change to overcome what is really useful. It has been said, for instance, that if a specific name be derived from a character which is afterwards discovered to be a generic one—as, for instance, *Leicistus spinibarbis*, *Loricera pilicornis*; or, if such name be derived from a sexual character—as, for instance, *Eucera longicornis*, *Eulophus ramicornis*, *Eulophus damicornis*, *Eulophus pectinicornis*, &c.; or, again, if a name has been employed indicative of the habitation or place of capture of an insect, and it is afterwards discovered that the supposed habitation was merely accidental—as, for instance, *Curculio lapathi*; or it be discovered that the insect is not confined to the supposed locality—as, for instance, *Agonum Austracum*, *Raphidia Londinensis*—that in all, or any of these cases, it is necessary that new specific names should be given to these insects. We, however, see no necessity for any such step: *Loricera pilicornis* is known throughout the entomological world under that name. The object for which specific names are given to animals is therefore completely obtained; and if we would change this name, and give it another strictly referable to some specific peculiarity, we cannot see what there is to prevent a would-be reformer of names from throwing down the hundreds of names, derived from the heathen mythology, given to insects, and substituting others of his own in their stead. Let us not, however, be understood to advocate error, even though long perpetuated.

The name of the author by whom an insect was first described and named, is generally placed in an abbreviated manner after the specific name. Thus the insect described by Linnæus under the name of *Carabus intricatus*, is spoken of as *Carab. intricatus*, Linn. Sometimes, however, when an insect has been removed from the genus in which it was originally placed, the new generic name is written, and the name of the person by whom the removal was made is added after that of the species. Thus the *Cychnus rostratus*, Fabr., was originally the *Tenebrio rostratus*, Linn.; but Fabricius removed it to the genus *Cychnus*. Here, however, an evident injustice takes place, as the name of the original describer of a species ought always certainly to follow

his own name. This difficulty might be obviated in two ways: either by writing the names of the last-mentioned insect, for example, thus—*Cychnus*, Fabr., *rostratus*, Linn.; or, more correctly, thus—*Cychnus rostratus*, Fabr. (*Tenebrio*, p. Linn.)—the letter *p* standing for the word part.

Generic names are, for the most part, derived from the Greek, and are generally indicative of some peculiarity of the genus. Thus the genus of bees, *Macrocera*, derives its name from two Greek words, *macro*, long, and *keras*, a horn; the antennæ being very long in the males. In like manner we have *platycerus*, broad-horned, &c. &c. Many of the Linnæan generic names are, however, destitute of any direct application to the insects which such genera contain, this author having employed the old natural history names, usually to be met with in the early authors in the most senseless manner. Indeed, this could not be avoided in many instances, from the vague manner in which the names had been employed; and hence Linnæus, anxious to enlist them all again into the service of natural history, hesitated not to employ them for objects which probably had not the least connexion with those to which they had been applied by the ancients. The universal adoption of the Linnæan nomenclature throughout the zoological world has rendered these blemishes too trifling to cause any confusion to originate in consequence of their adoption. For the like reason, and in order to prevent the equally great confusion which would arise by employing several names for the same animal, naturalists have adopted the plan of retaining that first proposed, unless it should happen to be evidently incorrect, the subsequently proposed names sinking into synonyms.

We will now, in conclusion, lay before the reader a short alphabetical list of the chief entomological authors, with a concise notice of their chief works, which are deemed of standard merit, and which no entomological library should be destitute of. There are a great number of names which we have necessarily omitted, the following being the most eminent only of the writers upon this branch of natural history.

ARISTOTLE.—The father of natural history. He lived about the year 330, B. C., and devoted considerable attention to the natural history of insects, which he separated, under the name of *Entoma*, from the *Crustacea*, which he called *Malacostraca*, and divided into three sections: 1. Those with wings, *Pterota*, or *Ptilota*; 2. those with occasionally wings; and, 3. those destitute of wings. In the first were comprised various subdivisions, admirably constructed, including the present orders, *Coleoptera*, *Diptera*, which two names are still retained; and others corresponding with the *Hemiptera*, *Lepidoptera*, *Diptera*, &c. In the second were placed the ant and the glow-worm; and in the third, all wingless insects.

AUDOUIN (Mons. Victor).—Professor of entomology at the Jardin des Plantes, Paris; author of numerous detached entomological memoirs; but especially known by his invaluable researches upon the structure of the thorax.

BOISDUVAL (Mons.).—A French entomologist, especially distinguished for various works upon *Lepidoptera*; the most valuable of which is his *Natural History of Lepidopterous Insects*, the first volume of which has just appeared, forming part of the *Suites à Buffon*.

**BURMEISTER (Dr. Hermann).**—A young Prussian entomologist of the highest promise. His works exhibit profound erudition, an admirable ingenuity and correctness in the anatomical details, and the greatest carefulness in the elaboration of his materials. He has published various memoirs of great merit; but is best known by his *Handbuch der Entomologie*, or *Manual of Entomology*, a very useful introductory work, in which a great quantity of materials, scattered over numerous miscellaneous works, is brought together, and admirably digested. We have already alluded to the translation of the first volume of this work, by Mr. Shuckard. The second volume treats upon the descriptive portion of the *Hemiptera* and *Homoptera*.

**CRAMER.**—A Dutch author, distinguished for his beautiful work, in quarto, upon exotic butterflies, in five volumes; commenced in 1779.

**CURTIS (John).**—An English entomologist, and author of *British Entomology*, or *Illustrations and Descriptions of the Genera of Insects found in Great Britain and Ireland*; the most elegant periodical work hitherto published. Each genus is illustrated by a coloured figure of one of the species, and with the details of the mouth and antennæ. A figure of a plant is added, upon which, in many cases, the insect is found.

**CUVIER (George Leopold Christian Frederick Dugobert, Baron).**—The greatest zoologist of modern days; born in 1769, in Alsatia; died at Paris, in 1832. In his *Traité Élémentaire*, and *Anatomie Comparée*, he carefully investigated the comparative structures of the annulose animals, and separated the *Crustacea* as a class from insects. In his celebrated work, *Le Règne Animal (The Animal Kingdom)*, the details of the entomological portion were executed by Latreille.

**DE GEER (Charles, Baron).**—A Swedish naturalist; born in 1720; known by his admirable *Mémoires pour servir à l'Histoire des Insectes*; a work in seven quarto volumes, with a great number of plates, in which the most ample details of the structure and metamorphoses of a vast number of species are given. Mac Leay calls him the prince of entomological authors.

**DEJEAN (M. Le Comte).**—A French entomologist, and the possessor of one of the most extensive collections of *Coleoptera* ever yet made. He has published, 1. a catalogue of his *Coleoptera* (the second edition is now in course of publication); 2. a description of the species of predaceous land beetles (*Cicindelidæ* and *Carabidæ*), in six octavo volumes, and (in conjunction with M. Boisduval) a description of European beetles, now in course of publication.

**DUFOUR (Mons. Léon).**—A French author, still living; distinguished for the great extent of his anatomical investigations upon insects, illustrated by figures drawn by himself. They are published in numerous foreign periodicals, especially in the *Annales des Sciences Naturelles*.

**ESENBECK (Dr. Nees Von).**—Professor of natural history at Breslaw; author of various memoirs upon the minute parasitic *Hymenoptera*; of which his recently published "*Hymenopterorum Monographiæ*" are the most valuable.

**FABRICIUS (Johann Christian).**—A German entomologist, pupil of Linnæus, and professor at Kiel in Holstein; born 1747; died, 3rd of May, 1810, aged  
NAT. HIST.—VOL. II.

63\*, especially distinguished as the founder of the Cibarian mode of distribution of insects (established upon the structure of the mouth); but more deservedly known and cited as a most extensive describer of species of insects. His chief works are *Entomologia Systematica*, in four vols., 8vo., commenced in 1794, and in which those species of all orders with which Fabricius had become acquainted in his numerous voyages, are described. He visited England several times, and was on terms of friendly intercourse with Sir Joseph Banks, &c. Subsequently he published as distinct works the *Systema Eleutheratorum (Coleoptera)*; *Antliatorum (Diptera)*; *Piezatorum (Hymenoptera)*, and *Rhyngotorum (Hemiptera, Homoptera)*.

**FALLEN.**—A Swedish entomologist, chiefly distinguished by his works, entitled *Diptera Sueciæ*, and *Hemiptera Sueciæ*, &c.; in which the species of these and some other orders found in Sweden are carefully described.

**GEOFFROY.**—A French author, contemporary with Linnæus; especially remembered on account of his introduction of the variations in the number of tarsal joints, as affording sectional groups in the order *Coleoptera*. His chief work is entitled "*Histoire abrégée des Insectes*," &c. Paris, 1764, 2 vols., 4to.

**GRAVENHORST (Dr. J. L. C.).**—Professor of Natural History at Breslaw, author of various works upon the *Brachelytra (Staphylinidæ)*, and also upon the *Ichneumonidæ*. *Ichneumonologia Europæa*, in three large octavo volumes, is his most valuable work.

**GUÉRIN (Mons. F. E.).**—A French naturalist and artist, author of numerous detached Entomological Memoirs, with beautiful illustrations; but especially distinguished by his *Iconographie du Règne Animal*, in which types of all the leading genera of animals are figured, with an infinity of details of structure.

**GYLLENHAL (Leonard).**—Author of a very valuable work in four volumes, octavo, entitled *Insecta Sueciæ*; but comprising only the beetles found in Sweden. His descriptions are admirable.

**HAWORTH (Adrian Hardy).**—An English entomologist, founder of the old Entomological Society, and author of *Lepidoptera Britannica*, a work consisting of careful descriptions of all the species of lepidopterous insects with which the author was acquainted. Died in 1834.

**HUBER, F.**—A Swiss entomologist, distinguished for his interesting series of *Observations upon the Economy of the Bees*.

**HUBER, P.**—Equally distinguished with his father for his extensive series of *Observations upon the Economy of the Ants*. His *Memoirs* have been translated into English.

**HUBNER.**—A German entomologist, author of a valuable work containing figures and descriptions of European *Lepidoptera*. (*Der Sammlüg Europaischer Schmetterlinge*), in quarto.

**JURINE (Louis).**—A Swiss entomologist, author of a valuable work upon the *Hymenoptera*, in which the structure of the veins of the wings was employed to characterise the genera, entitled *Nouvelle Méthode de classer les Hyménoptères et les Diptères*. Vol. 1, *Hyménoptères*. Geneva, 1807, quarto.

\* There is some confusion in entomological works as to these dates. Those given above are derived from information given to the writer hereof by Dr. Fabricius of Kiel, son of the entomologist.

**KIRBY (Rev. W.).**—The father of English entomologists, author of a great number of detached Memoirs, and especially distinguished by his Monograph upon the English Bees, a most invaluable work, and a model for all subsequent monographers. He likewise published, in conjunction with W. Spence, an Introduction to Entomology, in four volumes, 8vo., a work of the greatest research. His Memoirs upon the Strepsiptera, the Genus Apion, and his Bridge-water Treatise, are also to be noticed.

**KLUG (Dr. Frederick).**—A Prussian Naturalist, conservator of the insects of the Berlin Royal Museum, particularly devoted to the Hymenoptera, and distinguished by his Memoirs upon the Tenthredinidæ (*Blattwespen*), published in the Berlin Transactions, and his Jahrbucher der Entomologie, &c.

**LAMARCK (Jean Baptiste de).**—A French naturalist, chiefly distinguished for his works upon the invertebrated animals, of which the most valuable is the *Histoire Naturelle des Animaux sans Vertèbres*, présentant les Caractères généraux, &c., in seven vols., 8vo. Paris, 1815. The class *Arachnida* was separated from the insects by this author.

**LATREILLE (P. A.).**—Professor of Entomology at the Jardin des Plantes, Paris. Born 29th of November, 1762. Died 6th of February, 1832. One of the most distinguished of modern entomologists, whose writings for nearly half a century have tended in the highest degree to improve the science which he so ardently loved. From the publication of his *Précis des Caractères génériques des Insectes*, published in 1796, until that of his *Cours d'Entomologie*, he ceased not to labour towards the accomplishment of a natural classification of insects, and to a perfect investigation of the general structure. His most valuable works are *Genera Crustaceorum et Insectorum*, in four volumes, 8vo., and his *Histoire générale des Insectes*, in fourteen volumes, 8vo.

**LINNÆUS (Carl von).**—A Swedish naturalist of the greatest celebrity. Born 24th of May, 1707, at Roeskult in Sweden, and distinguished as the founder of modern Zoological Classification and Nomenclature. His works appeared in succession from 1735 to 1770, each being advantageously remodelled. His *Systema Naturæ*, in which all the animals, plants, and minerals with which the author was acquainted, and his *Fauna Sueciæ*, in which the animals of Sweden were described, are most constantly cited. Of the former work twelve editions appeared in the lifetime of the author; the last of which was published in 1766, and which is considered as his most valuable work.

**LYONNET (Pierre).**—Author of one of the most elaborate treatises ever published, bearing the title of "*Traité de la Chenille qui rouge le Bois de Saule*," in which the anatomy of the larva of the goat-moth, *Cossus ligniperda*, is described and illustrated in the most complete manner. It was published in 1760, in one volume, 4to., containing 615 pages and eighteen plates. The anatomy of the pupa and imago, but in a comparatively imperfect state, have been lately published.

**MAC LEAY (Wm. Sharp).**—Author of the *Horæ Entomologicæ*, a most remarkable and profound treatise, in which the relations of animals are treated upon in a peculiar manner. The work also contains a classification of the Lamellicorn beetles. He has also published the first part of the *Annulosa Javanica*, containing a portion of the *Coleoptera* collected in

Java by Dr. Horsfield, whose *Lepidoptera Javanica* may be considered as a continuation of the same work.

**MACQUART (Mons. J.).**—A French entomologist, who has confined his attention to the dipterous insects, and has published numerous Memoirs upon those found in the North of France, in the Transactions of the Natural History Society of Lille. Likewise two volumes containing A General System of Dipterology, with plates, in the series of works termed *Suites à Buffon*.

**MARSHAM (Thomas).**—Author of *Entomologia Britannica* (London, 1802), of which only the first volume, containing the *Coleoptera* of Great Britain, was published. Being, in consequence of the difficulty of intercourse with the continent during the war, unacquainted with the labours of his contemporaries, many of the species which he described had previously received names, so that those which he proposed have been rejected.

**MEIGEN (J. W.).**—A German author, who has confined his attention to the dipterous insects of Europe, which he has carefully described in his *Systematische Beschreibung der bekannten Europ. Zweiflug. Insekten*. Aix-la-Chapelle, 1818, six volumes, 8vo. During the last autumn he exhibited to the writer hereof a complete series of drawings of all the species which he has described. It is greatly to be hoped that this valuable collection will be published.

**OLIVIER (Guillaume Antoine).**—Author of various Entomological Memoirs, and especially of the Entomological articles in the great French *Encyclopédie Méthodique*, in which great numbers of new species are described; and likewise of the *Histoire Générale des Insectes*, of which work, six quarto volumes, with many plates containing the *Coleoptera* only, have appeared.

**PANZER (G. W.).**—A German entomologist, author of many works, but especially known by his *Fauna Insectorum Germaniæ initia*, a very extensive work, in which each species is figured. There were 110 numbers of this work published during the lifetime of the author, each containing 24 plates; and since his death, Ahrens and Herrick Schaffer have commenced supplements.

**PAYKULL.**—A Swedish author, published in 1800 a valuable work, in 3 volumes, 8vo., upon the *Coleoptera* of Sweden, the descriptions of which are very exact. He also previously published detached Memoirs upon the *Curabidæ* and *Staphylinidæ*, *Curculionidæ* and *Histeridæ*.

**PICET.**—A Swiss author, who has lately published a very complete work upon the phyganea or caddice flies, (order *Trichoptera*, Kirby).

**RAY (John).**—The first true systematist and author of *The Wisdom of God, in the Works of the Creation*, and of a quarto volume, entitled *Historia Insectorum*, London, 1710, and a tract with the title *Methodus Insectorum, seu Insecta in Methodum aliqualem digesta*.

**REAUMUR (Rene Antoine Erchault de).**—Born in 1683, at La Rochelle. He was a most astonishing genius, devoting his attention to various branches of philosophy; but the most elaborate of his works was that published under the title of *Mémoires pour servir à l'Histoire des Insectes*, in 6 volumes, 4to., containing 3,672 pages, and 267 plates. This immortal work is so constantly cited in every work of

entomology, in which the habits and manners of insects are introduced, that it would be useless to say anything in its praise. Its distinguished author died in 1757.

REDI (Francisco).—An Italian naturalist, who, by his work published at Florence, in 1668, entitled *Experimenta circa Generationem Insectorum*, completely overthrew the doctrine of spontaneous generation.

ROSEL VON ROSENHOFF (August Johann).—A German naturalist, author of various works upon entomology, and particularly a beautiful work in 4 volumes, 4to., with many plates, in which the habits and transformations of many interesting species of insects are recorded. It appeared in 1746, and was continued until 1761.

SAVIGNY (Jules Cæsar).—A French naturalist, distinguished by his elaborate researches into the comparative structure of the mouths of insects and other annulose animals, and author of *Mémoires sur les Animaux sans Vertèbres*, and of the plates which illustrate the annulose portion of the magnificent French work upon Egypt, undertaken by order of Napoleon. The labours of this distinguished naturalist have cost him his eye-sight.

SAINT FARGEAU (M. le Comte Lepelletier de).—A French entomologist, who has confined his attention to the *Hymenoptera*, distinguished by his *Monographia Tenthredinetarum*, by numerous articles in the last volume of the *Encyclopédie Méthodique*, and by his work upon the *Hymenoptera* in general, forming a portion of the *Suites à Buffon*.

SCHONHERR (C. S.).—A Swedish entomologist, distinguished by an elaborate work, in course of publication, upon the *Curculionidæ*, in 6 volumes, 8vo., and which, in fact, forms a continuation of his *Synonymia Insectorum*, a work in 4 volumes, 8vo., confined to the synonymy of the *Coleoptera*.

STEPHENS (James Francis).—An English entomologist, and author of a most laborious, systematic, and synonymical Catalogue of English Insects, of all the Orders, and of Illustrations of British Entomology, consisting of descriptions thereof. Of the latter work, the coleopterous, lepidopterous, and orthopterous portions are now completed, and the *Hymenoptera* are in course of publication.

SWAMMERDAM (John).—One of the fathers of entomology, chiefly distinguished by his *Biblia Naturæ*, a work in 2 volumes, folio, with 53 plates, in which the transformations of many insects were completely traced from their various stages. This work, therefore, in conjunction with that of Redi, completely established the real nature of insect metamorphoses. It has been translated into English by John Hill, whose edition was published in 1758.

WIEDEMANN (G. R. W.).—Professor of Natural History at Keil, and successor of Fabricius, whose attention has been chiefly confined to exotic *Diptera*. His chief work, *Aussereuropäische Zweifl. Insekten*, is in 2 volumes, 8vo., and was published in 1828.

INULA (Linnæus). A large genus of annual and perennial herbs, chiefly natives of Europe. They bear yellow discous flowers, and belong to *Compositæ*. They thrive in any common garden soil.

IODAMIA (of De France) is a fossil shell united to the genus *Birostrites*, of which it may be considered only a species.

IPOMCEA (Linnæus). A very extensive genus of annual and perennial climbing plants, from almost all parts of the world. They are nearly allied to con-

volvulus, and some of them bear remarkably handsome flowers. Class and order *Pentandria Monogynia*, and natural order *Convolvulaceæ*. They are, in cultivation, usually trained to columns or on trellis-work, and are easily managed plants, whether in the stove or greenhouse.

IPS (Herbst). A genus of coleopterous insects belonging to the section *Pentamera*, and family *Engidæ*, having the body of an oblong-oval form, and depressed, with the third joint of the antennæ longer than the second, and the club large and rounded. These insects are generally found under the bark of decayed trees, where they feed upon sap, for lapping which the terminal lobe of the maxillæ is elongated. The species are chiefly confined to Europe, and are generally ornamented with red or yellow spots upon a black ground. The British species (of which four have been described, but to which number another, from the neighbourhood of Edinburgh, captured by the Rev. Mr. Little, must be added) are generally rare, and do not exceed one-fourth of an inch in length. The type of the genus is the *Silpha 4-pustulata* of Linnæus, which is of a black colour, with four irregular red spots on the elytra.

IRIDEÆ, a natural order of plants, comprising already above thirty-six genera, and between four and five hundred species. Many of the most beautiful gems of flora are found in this order, namely, *Iris*, *Lilia*, *Crocus*, *Tritonia*, *Gladiolus*, *Antholyza*, *Tigridia*, &c. &c., they are all plants of peculiar interest as to the modifications of structure they present, both in the organs of vegetation and fructification. They form a very natural assemblage, in all of which, excepting the crocus, the leaves are equidistant, and rise in general from that kind of stem called a *rhizoma*, either extended, as in *iris*, contracted as in *crocus*, or still less developed, as in those which have fibrous roots; that is, where the inferior caudex is at once divided from the crown into fibres without forming even the plate of the crocus, which is called a *lecees* if very thin, or a *combis* if collected into a thicker mass. The *Irideæ* are easily known by the outward dehiscence of their erect anthers. The germen is inferior and three-celled, the placenta axil, the ovules many, and the albumen hard or horny. Although the crocus alone has aromatic stigmas, a great uniformity prevails among all these plants in the properties of other parts. Their fleshy root stocks contain much fecula, impregnated with an acid bitter principle; hence, both *Iris Germanica* and *pseudacorus* have been employed as purgatives and emetics; and *I. Florentina*, from its agreeable odour, to make tooth and hair-powder, and to keep up the discharge from issues. Pallas says, that the roots of *I. dichotoma* are eaten in Siberia; and, according to Thunberg, the Hottentots roast and eat the roots (or *rhizomas*?) of *I. edulis*. The seeds of *I. pseudacorus*, when roasted, form a very excellent substitute for coffee.

IRIDINA (Lamarck). Some slight difference in the formation of the hinge of these shells induced Lamarck to separate them from the genus *Anoden*, to which they have since been united by more recent writers; the substance of the shell is also constantly more solid than that of the *Anoden*. It has a brilliant rose-coloured, peachy interior, particularly iridescent, and is found in the rivers of warm countries. Until the more extended researches of recent travellers, this shell was of great rarity; and in Du Bois' Epitome of Lamarck's arrangement, only two examples are named: one in the present Provost of Etou's

splendid cabinet, the other in that of the late Earl of Tankerville.

**IRIS** (Linnæus). A beautiful and very numerous genus of herbaceous perennials, belonging to the class and order *Triandria monogynia* of Linnæan botany, and to the natural order to which it gives a title, viz. *Irideæ*; one or other of the species are seen in every cottage garden; the generality being hardy, and increase themselves spontaneously. Some of the foreign sorts require the care of the florist, as the Persian and all the bulbous-stemmed sorts. The French national emblem, *Fleur-de-lis*, is found here.

**IRON**. The most important varieties of this mineral will be described under the general article **MINERALOGY**.

**ISATIS** (Bauchin), a genus of herbaceous annuals and biennials, natives of Europe, belonging to *Cruciferae*. One of the species is found wild in England, viz. the *I. tinctoria*, and cultivated as a dye, under the name of woad. It was, before the introduction of indigo, a plant of considerable commercial importance, and extensively cultivated in Somersetshire, especially about Glastonbury, which town received its name from the Celtic word *glas*, signifying blue. The ancient Britons are said to have painted their bodies with the blue colour obtained from this plant.

**ISOCARDIUM** (Lamarck; CHAMALOR, Linnæus). The molluscs constituting this genus have been separated from the genus *Chama* of Linnæus, and the genera *Cypriocardia* and *Cordilia* of Lamarck's first arrangement of conchology, not only on account of the peculiar shape of the cardinal teeth, which principally guided his classification, but also on account of the singular and graceful curvature of the umbones, which are spirally turned on either side each valve in the form of what is called familiarly a fool's-cap, from which is derived the trivial English name of the type of this genus, and is found in the European Seas; the others inhabit the China and Indian Seas. The *Isocardia*, first described by Moltke, was a few years since of great rarity and price, but is now within the reach of every collector's purse. The general description of shells of this genus is its being equivalve, heart-shaped, globose, the umbones distinct, and spirally recurved to the side of each valve; two flat primary teeth, one of which is bent and inserted under the umbo; a lateral prolonged callosity or lengthened tooth; and the ligament external and forked on one side. De France enumerates six fossil species, one of which is precisely analogous.

**ISOLEPIS** (R. Brown). A genus of annual and perennial grass-like plants, belonging to *Cyperaceæ*. Common in British ditches and bogs, as well as in similar places in foreign parts.

**ISOPODA** (Latreille). An order of crustaceous insects belonging to the sub-class of *Edriopthalmous malacostraca*, and embracing the Linnæan genus *Oniscus*, with the numerous sectional and generic groups separated therefrom. It is distinguished by the hard envelope of the body, the eyes not raised upon footstalks, the body divided into a series of nearly equal sized and generally flattened segments, and the legs of nearly equal size, and fourteen in number, the anterior pairs not being cheliferous, or armed with large claws. These characters will readily distinguish them from the leaping shrimps (*Gammarus*, &c., order *Amphipoda*), and from the order *Lamodipoda*, as well as from the great division of *Podopthalmous crustacea*. The legs are terminated by a short curved hook or

nail; the under surface of the abdominal portion of the body is furnished with flattened appendages or plates, having the edges fringed with fine hairs, serving, as is supposed, for respiratory organs, and covered by a larger pair. The body is generally flattened and of an oval form, being broader than it is thick. The internal pair of antennæ are almost obsolete in some of the most aberrant species of the order which are not aquatic. The females carry their eggs for a considerable period in a membranous bag, under the breast or between the pectoral scales. The young when hatched are very similar in form to their parents, and undergo scarcely any other change than that of an increase of size produced by the occasional shedding of the outer envelope of the body. The greater number of species inhabit the water, some of them being parasitic upon fishes. The terrestrial species also require a certain degree of moisture, in order to preserve their branchiæ in a fit state for respiration.

Latreille divides this order into six sections as follows:—

1. *Epicarides*—destitute of eyes and antennæ, legs unfitted for locomotion. This section comprises only a single genus, *Bopyrus*, Latreille, which is often to be found under the shell of the prawn.
2. *Cymothoidæ*—four antennæ terminated by a multi-articulate slender thread, fore legs generally furnished with strong hooks. These are parasitic upon fishes. Genera, *Serolis*, *Cymothoa*, *Ichthyophilus*, *Æga*, and many other genera established by Dr. Leach, including the *Limnoria terebrans*, which is so destructive in some of our ship yards.
3. *Sphæromidæ*—antennæ four, abdomen with two articulations, swimmerets composed of two plates, the lower being moveable. Genera, *Zuzara*, *Sphæroma*, and other genera of Dr. Leach.
4. *Idoteidæ*—antennæ four, placed on the same line, internal small, abdomen with three articulations, destitute of lateral swimmerets. Genera, *Idotea*, *Stenosoma*, *Arcturus*.
5. *Asellidæ*—antennæ four, inserted in two lines, abdomen composed of a single articulation, without lateral swimmerets, and terminated by two long and slender styles. Genera *Asellus*, *Oniscoda*, &c.
6. *Oniscidæ*—internal antennæ almost obliterated, abdomen six-jointed with two or four terminal appendages; some are terrestrial. Genera, *Ligia*, *Oniscus*, *Porcellio*, *Armadillo*. A figure of the last named genus will be found in our article **CHILOGNATHA**.

**ISOPOGON** (R. Brown). A genus of evergreen shrubs from New Holland, belonging to the class *Tetrandria* and the natural order *Proteaceæ*. These are ornamental plants, but require much care in keeping healthy, owing to their being easily injured by too much water at the root. They may be propagated by cuttings, but with difficulty, if they get too damp.

**IVY**, a well-known British plant. See **HERBERA**.

**IXIA** (Linnæus). A beautiful flowering genus of Cape bulbs, belonging to the *Irideæ*. The best soil for the *ixias*, of which there are many splendid species, is a mixture of sandy loam and leaf-mould, or moor-earth. They require no water after they have done flowering. They should be fresh potted in October, and set in a cold frame well protected from frost.

When they have commenced growth they may be removed to the greenhouse to perfect their flowers, in doing which they must be regularly watered. A cold pit, or close under a south wall, is favourable to their growth, provided they be defended against frost. They are propagated by offsets.

**IXORA** (Linnaeus). A genus of fine flowering evergreen shrubs, found every where in the eastern parts of Asia. Class and order *Tetrandria Monogynia*, and natural order *Rubiaceæ*. Generic character: calyx small, four-cleft; corolla-tube long; limb regular, four-lobed, spreading. Stamens almost setting on the throat of the limb, alternating with the lobes thereof. Style lengthened out, stigma double. Berry two-celled, and two-seeded. This is one of the finest of our stove plants, and when grown in a moist heat, kept free from insects, and properly attended to, and not plunged in the bark-bed, always flowers in perfection. It is increased by cuttings.

**JABIRU**. A genus of American birds chiefly inhabiting the marshy places of the tropical parts of that continent; and bearing some resemblance to the herons, but much more to the storks. See the article *MYCTERIA*.

**JACAMAR** (*Galbula*). A genus of *Zygodactylic*, or climbing birds, which reside chiefly in trees, but are not so decided climbers as many of the order. They are in so far related to the kingfishers; and, like them, they have the anterior toes in great part united, so that, though several naturalists rank them with the zygodactylic birds, the real structure of their feet is syndactylic. As is the case with the kingfishers their tarsi are short, their feet altogether of feeble structure, and evidently not intended for performing any very important office in the economy of the birds. They rest upon trees, and build their nests in the lower branches; but they feed on the wing, chiefly, if not exclusively, upon those insects which hover over water and humid earth; and thus the birds are found only in marshy places, which in such situations are very unfavourable to human life; and therefore, as is the case with our own kingfisher, the habits are not so well observed, because not so open to observation as those of many other birds. In finding their food, they keep to the air, and do not fish, even by twitching fishes out of the water; and thus their habits do not require the same smoothness of plumage as the kingfishers, but they have all a good deal of metallic lustre in their feathers.

The structural characters of the genus are: the bill long, straight, or slightly bent toward the tip, slender, four-sided, and without any notch or tooth; the nostrils placed laterally at the base of the bill, of an oval shape, and covered with a naked membrane for the posterior half of their length; the feet very short, with three or four toes, of which two are always turned to the front and united as far as the third joint; the wings of mean length, the first three quills increasing in length by stages, but the third shorter than the fourth and fifth, which are the longest in the wing; the tail consists of twelve feathers, of which the two lateral ones are very short.

These structural characters indicate a peculiarity of action in the birds, which confines them to localities which are rather limited; as they must find their food without any very severe degree of labour. The feet, as we have already observed, are quite inefficient for any very important active purpose; and they are

not adapted even for that slow climbing motion from branch to branch which characterises the parrot tribe and other tree climbers; and as little can they cling to the upright bole of a tree, like the woodpeckers, or run along like the creepers, and other birds which are active in catching insects upon the bark. As little does the structure of their wings suit them for coursing their insect prey through the air, by rapid motions and sudden wheelings and evolutions, such as those made by the swallows and bee-eaters. Their organs of motion are all fitted for short flights, and frequent ascendings and descendings; and this kind of structure and of flight naturally confines them to those situations in which slow-flighted insects are found in sufficient abundance. Of course it is only in those rich and humid parts of the tropical countries which may be said to be in a state of perpetual production, without any winter's repose, and free from drought, as take place in the less humid districts of the same climates, that these birds can be in a situation properly adapted for them. Hence it does not appear that they migrate to any considerable distance. Our knowledge of them is, however, far from perfect, and we must receive with caution many of the accounts which have been given of them. They inhabit the deepest recesses of the forests, and thus they are but rarely seen; and different from very many of the birds of tropical forests, they are not much heard. Their voice is very feeble, being merely a sort of subdued hissing; and even this is practised only during the breeding time, which we believe is not confined to any particular season of the year, which licence indeed extends to very many of the forest birds of tropical countries. Generally speaking, they remain at perfect rest, and in perfect silence, on the twigs or leaves of the trees, always as solitary individuals, and never in flocks, or even in societies of any extent. From those resting places they sallies forth with very rapid but very short flight, in order to capture those insects which are sporting over the water. They never rise to any great elevation when on the wing; and their short flights are taken in straight lines, generally sloping upward or inclining downward, for either of which they are remarkably well adapted by the peculiar structure of their wings and tail. It has been supposed that some species at least of the jacamar deposit their eggs in the nests of other birds, something after the manner of the cuckoo of Europe, but the fact is not clearly established. All the known species are understood to be natives of America only. They admit of division into two sub-genera, in consequence of the different number of toes in each.

**JAMAICA JACAMAR** (*B. Galbula grandis*) is a native of that country after which it is named. It is about ten inches in length. The upper parts are golden green, with reflections of copper and bronze. The first quills are brown: the upper tail-coverts green, the lower ones ash colour with violet reflections. The feathers at the opening of the gape are copper red; the chin white; the throat and under parts red; the bill and feet black, the former nearly straight and resembling that of the king-fisher. This one has two toes turned to the front and two to the rear, the latter free, but the former united.

**LONG-TAILED JACAMAR** (*G. paradisea*). This species is longer than the former, but the greater length is in the tail rather than the body. The upper part is blackish brown with a play of colours; the top of

the head is brown; the chin, the sides of the head, the breast, and all the under parts are blackish, but marked with white spots on each side of the belly; the quills and tail feathers are violet black with a play of colours; and the two middle feathers of the tail are considerably longer than the rest, and each one toward the side is shorter than the one within it. The bill and feet are black. The colours of the female want the reflections which characterise the male; and the two middle feathers of the tail are also shorter in that sex.

**YELLOW-BILLED JACAMAR** (*G. flavirostris*) has the upper parts of golden green with very brilliant copper coloured reflections. The front and region of the eyes blackish brown with bright metallic lustre. The primary quills brown with the basal parts and the inner webs yellow. The tail feathers regularly staged, with the two middle ones golden green, and the remainder russet. The chin is whitish, the throat reddish, the breast copper green, the under parts bright red; and the bill yellow at the base, but black at the tip. The colours of the female are much duller than those of the male. The length of this species is about eight inches.

**WHITE-BELLIED JACAMAR** (*G. leucogaster*) is also about eight inches long, and has the whole bill, and also the feet black. The upper part golden green; the sides of the head dull blueish green; the quills and tail feathers golden green, margined with iridescent blue. The throat and belly are white, but all the rest of the under parts are golden green. The bill and feet are black.

**GREEN JACAMAR** (*G. viridis*). This species is also of the same size as the two preceding ones. It has the upper part of a very rich and brilliant golden green; the front and region of the eyes blackish brown; the top of the head, and the edges of the quills and tail feathers deep blueish green; the rest of the primaries blackish. The chin ash-colour, the throat white, and all the rest of the under parts russet. The under parts of this one are, however, subject to considerable varieties of colour in different individuals.

**THREE-TOED JACAMAR** (*G. tridactyla*). This species differs from the former in size, being only seven inches in length; and it differs more in the structure of its feet, by having only three toes, two to the front and one to the rear. On this account it has sometimes been classed with the bee-eaters, and at other times regarded as a separate genus. But its structure and habits are not like those of the bee-eaters, nor does it appear that there are any good grounds for regarding it as a distinct genus, at least in so far as its general manners are concerned. The upper parts are blackish brown with green reflections; the feathers on the crown, and at the base of the bill, are blackish brown, with produced margins of a reddish colour to their webs. The primary quills and tail feathers are brown, margined externally with golden green; the secondary quills are brown, with some mottling of yellow; the sides of the head are brownish ash; the chin yellow: the throat black; the middle of the breast and the belly white, with a rosy tint; the flanks and under coverts of the tail blackish, mottled with russet; and the bill and feet are blackish. Such are the few particulars at present known respecting this genus of birds; but as the very peculiar countries which they inhabit are beginning to be explored with equal zeal and ability, we may soon expect more complete accounts of them and their fellows of the woods.

**JACANA** (*P. Parra*). A very peculiar, and by no means uninteresting genus of birds, belonging to Cuvier's *Macrodactylic*, or long-toed family of *Echasiærs*, or stilt birds; and forming the most typical or characteristic genus of the family. In their habits they are somewhat allied to the rails and water-hens of our temperate climates; but they are all natives of warm countries, and possess the power of running lightly upon aquatic plants and herbage in far greater perfection than any of our birds.

The birds of this genus are very strikingly distinguished from all the other walking birds by the great development of their feet, which are in all the species, and in every part of the structure, very large and strong in proportion to the size of the bird. The tibiae are very long, stout, and naked of feathers for the greater part of their length; the tarsi are also very long and strong; and these two bones are, together, as long as the whole body of the birds, if not longer. The most remarkable part, however, is the great development of the toes and claws. These toes are four in number, three to the front, and one to the rear, all articulated at the same height on the tarsus, and perfectly free, or without membranes, to their very basis. They are furnished with very long claws, very little bent, and tapering to points, which are exceedingly sharp; and this peculiarity of the claw is more remarkable on the hind toes than on any of the rest. From this produced form and extreme sharpness of the claws, the French have given these birds the fanciful name of surgeons, though it does not appear that they exercise those keen weapons in any kind of phlebotomy, or in doing violence to any creature whatever; though, as we shall presently see, this very singular formation is by no means without its use in the economy of the birds. The body, as is the case in all birds which have a running or walking habit rather than a flying one, is borne with the axis nearly horizontal; and such is the extent of base obtained from the great production of the toes and claws, that it extends as far as from the breast to the posterior extremity of the body. The bill is of moderate length, not exceeding that of the head. It is straight, slender, slightly compressed, rather enlarged at the point, flattened at the base, where it extends into a sort of plate on the forehead, nearly in the same manner as in the coots, which also belong to this family. The mandibles are of unequal length, the lower one being the shorter. The nostrils are lateral about the middle of the bill, oval, and open through and through. The wings are of mean length, or rather long for the size of the bird; the first and second quills are of equal length, and the third is often the longest in the wing. One of the most remarkable appendages of the wing is a large horny spur, slightly curved, and very sharp-pointed, which is placed on the turn of the wing, and which might be used as a rather formidable weapon; but whether it ever is so used has not been determined. This formidable armature of the feet and the wings has, however, led some to conclude that these birds are of a pugnacious disposition; but the very reverse seems to be the case; for those who have had the best opportunities of observing them in a state of nature, represent them as being very peaceable birds, and very much attached to each other, especially the pairs, which show a very strong reciprocal affection. The birds are at all times difficult to approach, because of the lightness and agility with which they run upon the

floating leaves, and also through the tall aquatic grasses, and the ease with which, when necessary, they can throw themselves so far into the air as to be able to get on the wing. The great elasticity of their toes, and the rapid contraction of these by the bendings of the upper joints of the limbs, are the means by which this is effected. The keen points of the claws, too, enable them to take hold of a stem or a leaf, so as to form a point of support with very little pressure. The spur on the wing is not of such apparent utility, but it may also assist the bird in holding on upon the aquatic herbage until it has acquired a footing. Any one who has observed with what swiftness, neatness, and lightness, the common water-hen runs along a brook, when there is only here and there a straggling leaf or stem to afford support, can readily imagine how much more fleetly these birds, whose feet are so much better organised for such an office, can make their way over the waters; and consequently how difficult it must be to obtain a sight of them, more especially as the places which they inhabit are not the most tempting for human visitors. They belong to places where the growth and the production of food for them is constant; and therefore their breeding-time is not fixed to a particular season. From the attachment which the pair show for each other, and the fact of a pair being generally met with, it has been concluded, not only that the males are strictly monogamous, but that the unions are formed for life. When one is occupied, the other is always watching, and instantly gives the alarm-cry when danger is near; or if the alarm-call is given, not from the actual appearance of danger, but from the apprehension of it, the one which is called to responds that all is safe by a sort of subdued and murmuring cry, which has something very pleasant in it. During the day, these birds remain very silent, unless when they are disturbed by unwelcome visitors; but during the night, when they are in motion, their cries are heard at a great distance, and the sound is by no means agreeable. Their nests are formed in the thick tufts of marsh plants, in a very similar manner to those of the long-toed birds of Europe. They are built of rushes and other coarse aquatic plants, of which a great quantity is collected, and placed sufficiently high for being above any ordinary inundation. The hatch consists of four or five eggs, of a greenish colour, and mottled with small spots of dark brown.

The birds of this genus were once supposed to be natives of America only; but they are found in the marshy parts of all tropical countries. In central Africa, in India, in the Oriental Isles, as well as all the richer parts of tropical America. They are birds which are peculiarly characteristic of the places which they inhabit; and as they are rarely found in situations which are but occasionally covered with water, and which form the proper pastures of the cranes and storks, they are not much given to migration. Within their localities, their flight, when they do take the wing, is rapid; but they do not rise to great heights, or fly over long distances.

Their proper function in nature appears to be that of cleaning the leaves of aquatic plants, of which there are vast numbers in tropical countries, from insects and other small animals which are not available either to flying or swimming birds. They take up the waters as a pasture, when the fly-catchers, bee-eaters, and other birds which can use the wing rapidly, there leave off; and they quit them at that particular stage where

they become the pastures of ducks and divers, and other birds which seek their food at the bottom, or submerge in the free waters. We shall now very briefly notice the principal species, the habits of all of which, in so far as they are known, appear to be very much alike.

THE FAITHFUL JACANA OR CHAZA (*P. Chavaria*) is a South American species, and by no means rare either in the country bordering on the Caribbean Sea, or in the humid parts of Paraguay. It is about the size of a dung-hill cock, and stands about a foot and a half high. The toes are long, the legs are of a tawny colour, and the bill is dirty white; a red membrane extends over both sides of the base of the bill to the temples, in the centre of which the eyes are placed. The irides are brown; twelve blackish feathers, about three inches long, form a crest on the nape, and the neck is furnished with black down. The body is of a brownish colour, and the wings and tail are brownish black. The wings are furnished with two or three spurs on the turn, which are about half an inch in length. The under parts are dull brownish black, as are also the feathered parts of the tibia, which are however short in proportion to the naked parts. The toes are so very long, that they are apt to get entangled with each other when the bird walks on level ground at a faster rate than its usual marching pace, which is slow and measured. It is found about the rivers and inundated places, where it is understood to feed indiscriminately upon small animals and vegetable substances. According to the accounts, its instinct of attachment is turned to use in some parts of South America, where the inhabitants keep a single tamed one for the purpose of accompanying their domestic poultry, which it defends from birds of prey by means of the spurs on its wings. In these cases it is said never to desert its charge, but to accompany the poultry in all their movements, and defend them with the greatest bravery.

CHILI JACANA (*P. Chilensis*). This species is described as not being so aquatic in its habits as most of the species, and it resides on the low and rich plains, but not exactly in the marshes; and its food consists of insects, worms, and other small ground animals. It measures about ten inches in length; the upper parts are of a rich chestnut colour; the forehead, head, neck, breast, abdomen, and larger wing-coverts, are pure black; the sides, rump, and coverts, and feathers of the tail, are bright chestnut red; the quills of the wings are clouded with green and yellow, and have black tips; the lesser coverts are blackish, with white tips; the under coverts of the wings are reddish, with the webs of the feathers loose and flocculent; the bill is yellow, covered for the basal half of its length by a red membrane, which proceeds as far as the angles of the eyes; and then bending upwards, forms two lobes upon the forehead, which are not attached to the forehead, but bend in part over the base of the bill. Those appendages indicate a considerable connexion between these birds and poultry. The eggs are four in number, of a tawny colour dotted with black, and they are a little larger than those of a common partridge. The male and female are always found together near the nest, and they fight with great bravery in defence of their eggs and young. When they perceive any person approaching the place where their nest is situated, they at first conceal themselves in the grass or other herbage, but their watchfulness is not thereby abated;

and when they discover that the enemy has found out the nest, they dart upon him with the most determined resolution, and fight boldly in defence of their charge. During the day, where they can have the advantage of sight, they are perfectly silent, and they do not utter their cries during the night without some cause of alarm; but if any one passes, or any unwonted noise is made, their ear appears to be as quick by night as their eye is by day, and they instantly give their call, which is audible at a considerable distance. On this account, some of the Indian tribes employ them, during their wars, as sentinels against nocturnal surprises of the enemy; if even a single foe approaches, let him tread how lightly soever, the jacana is sure to give the alarm, and thus the purpose of the assailant is defeated.

COMMON JACANA (*P. jacana*) is of a rich maroon brown on the upper part, and the same colour on the under part, only more obscure in the tint. The head, neck, throat, and breast, are black with metallic reflections; the quills are yellowish green, with black borders; the bill yellow, and the frontal membrane reddish yellow. This membrane forms three lobes, which are not attached to the forehead, and it has two fleshy appendages at each side of the upper mandible. The spine on the angle of the wing is large, conical, and of a white colour: the legs are greenish grey: the length is about ten inches. The young have some white on the under part, are lighter in the colour, and of smaller size. This species is very generally distributed over the warm parts of America, and is common in Brazil, in Guiana, and in some of the West India Islands; it inhabits the borders of pools and rivulets almost invariably in pairs.

BRONZE JACANA (*P. anca*). This is rather a doubtful species, and is probably the same with the Brazilian jacana of some authors; and also with one or two others, which are known only in museum specimens, generally supposed to have been obtained from Brazil.

SENEGAL JACANA (*P. cinnamomia*). Is a native of Central Africa. It is maroon brown on the upper part and deep brown on the under: the head is black, the lower part of the neck white, the breast russet, the bill yellow with a blueish-grey frontal membrane.

INDIAN JACANA (*P. Indica*). Is found in Bengal

and other humid parts of India. The upper part is brownish ash, and the lower and also the head and neck blueish black; the quills are blackish violet; there is a white streak over the eye; the bill is yellow with a blackish-blue frontal appendage; there is a red spot at the angle of the gape; the feet are brownish; and the length is about nine inches.

CRESTED JACANA (*P. cristata*). This species is about ten inches in length: it is bronze green on the upper part, and has the head, the neck, the lower part of the back, the breast, and the belly, dull green; the rump, the flanks, the vent-feathers, and tail-coverts reddish brown; the larger coverts and primary quills of the wings blackish green; the feet and toes green with brown claws, the bill yellow, and the frontal appendage smooth, and of a crimson red. This species is found in Ceylon and other parts of the east.

LONG-TAILED JACANA (*P. Sinensis*). How this species came to get the name of "Chinese" it is not easy to say; because it inhabits not China but the eastern Archipelago. The upper parts are reddish brown, and the under parts deep purple brown; the head, the throat, and fore part of the neck are white, pencilled with black; the hind part of the head is black, and the back of the neck very rich golden yellow; the coverts of the wings are white; the primary quills black, and the secondaries white with black borders: the colours of these parts do not, however, appear to be constant; the tail feathers are black, and the four middle ones are longer than the rest, and pendent over them in a very graceful curve: the bill is blueish, and the frontal appendages and the feet are green; the spine on the wing is horn colour, and of moderate size. The total length is from eighteen to twenty inches, of which, however, a considerable portion is taken up by the produced feathers of the tail.

Such is a short list of the chief species of these very peculiar birds; and it is not a little remarkable, that while so many birds of decided migratory habits are confined to one or other of the two continents, these stationary birds should be found in both, and in both tropical parts of the eastern one. We have no reason to suppose that they passed from the one continent to the other, although their manners in both appear to be very similar.
